Translator Version 2

Upright reason dictates that the recipients of the good, of whatever type and level of beneficence it may be, must show gratitude and blessing to the beneficent person in every way possible, commensurate with the value of the beneficence. And one who has benefited all the people of the world — for example, one who invented a new instrument for the good of the world, or a good book — it is fitting for every discerning person, out of the obligation of love of fellow beings, to at least purchase it, so that the man will profit and his heart will be encouraged thereby to invent yet more good instruments in the world. And similarly, all other wise-hearted people will likewise strive and exert themselves to invent good things and instruments needed for the repair of the world and its perfection.

And therefore, whoever says: "What do I need this new instrument for?" — he does not act well towards the world. For if not for the man who invented it, where would you be? And what would your city do? And more than this, if the man did not exert himself, what would the world do?

— R. Pinchas Eliyahu Hurwitz, *Sefer HaBris HaShalem* (1797)

A note on the work

Johannes Hevelius's *Cometographia* (Danzig, 1668) is the major pre-Newtonian survey of comets. Drawing on his own careful observations of the comets of 1652, 1661, 1664 and 1665 from his rooftop observatory in Danzig, Hevelius examines the place, parallax, distance, formation and dissolution of comets, the changing shapes of their heads and tails, and above all their motion, which he argued followed curved, near-parabolic paths rather than straight lines. The work closes with a history of every comet recorded from antiquity to his own day, annotated by the author, and a universal table of comets. Its many engraved plates, cut by Hevelius himself, are among the finest astronomical illustrations of the century.

A note on the translation process

This translation was produced with the translation-pipeline. See the linked repository for details on the process.

A note on the references. A scriptural or bibliographic reference given in brackets or parentheses is, in most cases, an **editorial identification of an allusion rather than a citation printed in the source**. Books of this kind quote and weave scripture constantly without naming it, and the identification is supplied here as a convenience to the reader. Where the source does print a reference of its own, it is given as printed. **An identified allusion is not evidence that the author cited that passage** — look at the original before resting an argument on one.

This text is the product of a highly refined automated translation process. It has undergone only cursory human review and should not be treated as an authoritative or scholarly rendering. It is offered solely as a reference and reading aid — a way to make an otherwise inaccessible work approachable — and any passage of real consequence should be checked against the original source.

Notation and abbreviations

A few conventions have been applied uniformly throughout this translation, so that one quantity is always written one way. They change how a value is *written*, never what it is; where the printed source and this translation differ in notation, the source's own form is recorded in the editorial apparatus.

Numerals are Arabic, even where the source sets Roman ones. Roman numerals are kept only in headings, running headers and signatures, which are transcribed as printed.

Dates are given as year, month, day — *1572 November 11*. Dates are Julian, as the source gives them, and have not been converted to the Gregorian calendar.

Times are written with raised unit letters: $7^{h}\ 36^{m}\ 12^{s}$ for seven hours, thirty-six minutes and twelve seconds. An interval longer than a day carries a raised d — $3^{d}\ 7^{h}$. The degree and minute signs below are never used for time.

Angles are written with the conventional signs — 23° 27′ 30″. Early modern astronomy divides the degree sexagesimally and often runs to places for which modern writing has no common symbol; the orders used in this book are:

sign	order	the source's term
°	degrees	*partes*, *gradus*
′	minutes of arc	*scrupula prima*, *minuta*
″	seconds of arc	*scrupula secunda*
‴	thirds	*scrupula tertia*

A **sign** is 30° — one twelfth of the circle — and is written with a raised s: 5^{s} 3° 57′ is five signs and 3° 57′, that is 153° 57′. The source uses the sign both as a place in the zodiac and as a plain unit of 30° for a motion or a distance, and this translation keeps that distinction by writing the count rather than naming a constellation.

The signs of the zodiac. Longitude is reckoned eastward from the first point of Aries.

	Latin	English	longitude
♈	Aries	the Ram	0°–30°
♉	Taurus	the Bull	30°–60°
♊	Gemini	the Twins	60°–90°
♋	Cancer	the Crab	90°–120°
♌	Leo	the Lion	120°–150°
♍	Virgo	the Virgin	150°–180°
♎	Libra	the Scales	180°–210°
♏	Scorpius	the Scorpion	210°–240°
♐	Sagittarius	the Archer	240°–270°
♑	Capricornus	the Goat	270°–300°
♒	Aquarius	the Water-bearer	300°–330°
♓	Pisces	the Fishes	330°–360°

The Sun, Moon and planets.

	Latin	English
☉	Sol	the Sun
☽	Luna	the Moon
☿	Mercurius	Mercury
♀	Venus	Venus
♂	Mars	Mars
♃	Iuppiter	Jupiter
♄	Saturnus	Saturn

Abbreviations used in table headings: **Long.** longitude; **Lat.** latitude; **Decl.** declination; **RA** right ascension; **Alt.** altitude; **Az.** azimuth; **Asc.** ascension; **Diff.** difference.

Where a table in the source spreads one quantity across separate columns for degrees, minutes and seconds, those columns have been joined into a single column and the value written whole. Where a value runs to thirds and beyond, the columns are kept, since there the columns are the notation.

[Front cover of the binding: limp vellum with no title. A small oval armorial stamp stands at the centre.]

[Inside front cover: a Library of Congress bookplate, "THE LIBRARY OF CONGRESS / RARE BOOK COLLECTION", is pasted at the head. Below it, and partly hidden beneath it, is a later pencil note in German, a collation of the plates. It is only partly legible on the scan; what can be made out appears to read "title engraving; 34, of which 4 folding plates; 71 engravings in the text" [?].]

Diagram. Engraved frontispiece. In the night sky at upper left a comet trails its tail among scattered stars. At upper right an observatory terrace with a balustrade stands on a colonnaded building with a garlanded frieze; several figures on the terrace observe with a long telescope, a sextant and other framed instruments. Trees and hills fill the left middle ground, where a distant crowd points at the sky. In the foreground three robed men in caps gather at a draped table. The bearded man at left holds a scroll showing a circular diagram: a dark central disc, a ring of comets joined by a dotted path, and astronomical signs at the rim. The seated man at the centre points to a chart on the table drawn with concentric circles and a fan of radii about a radiant star, with planetary signs beside the inner arcs; a pair of dividers lies beside it. The man at right holds up a scroll showing a dotted semicircular track, a star, a fan of lines and a row of small comets. A globe on a stand stands at lower left, and a sextant-type instrument and a ring lie on the floor. The title is engraved in a scrolled cartouche at the foot of the plate.

- Left scroll, top and bottom: two crescent-moon signs (☾).
- Left scroll, upper right: one sign [?] — not resolved into a definite planetary sign.
- Left scroll, lower left: one sign [?] — not resolved into a definite planetary sign.
- Table chart, beside the inner arcs: about five planetary signs [?] — not individually resolved.
- Right scroll: no lettering seen.
- Cartouche: "JOHANNIS HEVELII / COMETOGRAPHIA." — Johannes Hevelius, *Cometography*.
- Below the plate frame, left: "Andr. Stech delin." — drawn by Andreas Stech.
- Below the plate frame, right: "L. Viſscher Sculps." — engraved by L. Visscher.

JOHANNES HEVELIUS'S COMETOGRAPHY,

setting forth the entire nature of COMETS:

namely their place, parallaxes, distances, origin and extinction, the various appearances and properties of their heads and tails,

and also their supremely remarkable motion —

all by means of a single hypothesis, and that one fixed and fitting.

In it, moreover, all the PHENOMENA and QUESTIONS concerning comets are deduced and demonstrated by evident reasons, and illustrated with a great many copper engravings.

Above all, the COMETS of the years 1652, 1661, 1664 and 1665, observed by the author himself with the greatest care, are set out and weighed at somewhat greater length and with greater care, and subjected to the most rigorous calculation.

To this has been added a HISTORY of all the comets recorded by historians, philosophers and astronomers from the creation of the world up to the present, enriched with the author's notes and comments, together with a special Universal Table of Comets.

With the privilege of His Sacred Imperial Majesty and of Their Royal Majesties of Poland and Sweden.

DANZIG.

At the author's own press and expense.

Printed by SIMON REINIGER.

IN THE YEAR 1668.

Diagram. Engraved headpiece above the dedication. A crowned king sits enthroned beneath a canopy, before a hanging strewn with fleurs-de-lis; his robe is also sown with fleurs-de-lis, and its train spreads across a tiled floor. Halberdiers in plumed helmets stand on either side of the throne. A kneeling man in a cloak lays an open book at the king's feet. At far left an armoured warrior in a plumed helmet, with a shield, stands among weapons, drums, standards and a pile of cannon-balls. At far right a helmeted female figure holds a spear and rests her hand on a shield bearing a Gorgon's head; beside her are an owl, a celestial globe on a stand, books, and a standard with a fleur-de-lis.

• No lettering was seen on the plate.

TO THE MOST POWERFUL, MOST INVINCIBLE, AND MOST CHRISTIAN KING OF FRANCE AND NAVARRE, LOUIS XIV, HIS BY FAR MOST GRACIOUS LORD.

Most Christian King,

the contemplation of a more hidden wisdom and of the science of the stars never more indeed flourished and grew than when it was the care and concern of princes and kings who held the sceptres of the world. This is perfectly well known to everyone from Ptolemy, King of Egypt; from Ulugh Beighi [Ulugh Beg], grandson of Tamerlane the Great; from the Emperor Rudolf; and from Kings Alfonso of Portugal and Frederick of Denmark, to pass over the rest.

We therefore now hope, with the assent of divine grace, for equally fortunate and immense progress in these sublime studies, since you, Most Christian King, deign to look down from the most exalted throne of Your Majesty, with so serene a countenance, both on the whole Republic of Letters and on the celestial disciplines as well. For Your Sacred Royal Majesty not only pursues all the sciences and liberal arts with ready love and honour, but also wishes, seeks and demands with the most ardent royal zeal that they be preserved, cultivated

and spread; so much so as to foster and stir up the more distinguished minds with its incomparable grace, and even to adorn them with the most splendid munificence, to draw them in and to bind them to itself. On this very great good fortune the whole learned world now congratulates itself most warmly, desiring nothing more ardently from the inmost depths of its heart than that this good fortune may last for ever, together with the felicity of Your Most August Majesty, which is to endure without end.

As for me, although I am the least among the measurers and cultivators of the stars and scarcely deserve the last place among them, I nonetheless, relying on your supreme clemency, revere no less, with the most submissive veneration, as is fitting, the illustrious grace and favour of Your Most Christian Majesty towards letters and men of letters, and I strive to proclaim and extol it for ever, publicly as much as privately; but above all because you, greatest King, me too, (although I have produced and published nothing but some slight specimens in the field of letters) — and a foreigner at that, lurking in obscurity — have not disdained, even though you see that your France is most fruitful in outstanding minds, most distinguished in every branch of learning, to draw me out into the fullest light and most graciously to receive me among men by far the most celebrated for fame and learning, whom you have judged worthy of your royal grace and protection, and indeed of your heroic liberality as well.

This has given me wonderful courage, so that I am now not afraid — something I should never have dared before — these Cometographic pages of mine, however very slight, yet gathered by me for the sake of illustrating and, if it can be done, even of enlarging the science of astronomy, with the most submissive and most obedient spirit, at feet of Your Most August Majesty. Although this little work is certainly far beneath so great a Monarch, yet since it is both of a noble and arduous subject and seems to look above all to the glory of the Supreme Deity and to the growth of divine Astronomy, Queen of the mathematical sciences, and since, besides, nothing else could come from my slender means on this occasion, I most humbly and most devotedly beg Your Sacred Royal Majesty to look upon it with a most serene countenance, and not to disdain to embrace its author himself further with Its most favourable grace and protection.

This royal indulgence — given Your Majesty's supreme benevolence and most ready goodwill towards our Uranian studies, such as they are, a goodwill long since well known to me — I too shall happily obtain, ful- ly confident as I am. Therefore I shall not only congratulate myself in private, but shall also be roused most greatly by the spurs, as it were, thereby applied, so that, aided by divine help, I may shortly complete, likewise under Your most happy auspices, my Celestial Machine and all my observations of the planets as well as of the fixed stars — drawn over many years, with the greatest labour and the utmost vigils, from the very aether with instruments not altogether unsuitable — together with a new catalogue of the fixed stars, enriched moreover with a great many new stars hitherto unknown and neglected, and bring them out

into the light; and so that I may once again attest before the learned world the most dutiful veneration of most humble gratitude that is owed to Your Sacred Royal Majesty.

To the immortal glory that Your Majesty has won by arms and trophies, as by letters most amply promoted, may there be added a felicity continued without measure: with a spi- rit sincere and most devoted I wish and pray for it.

Danzig, on the very day of the vernal equinox, in the year 1668.
Your Sacred and Most Christian Majesty's
most humble and most submissive
J. Hevelius.

Diagram. A circular engraved vignette, the only printed matter on the page. Above, a winged figure in flowing drapery flies among clouds, blowing two long trumpets, from each of which hangs a banner bearing three fleurs-de-lis under a crown. Below, a closed royal crown topped by a fleur-de-lis is borne on a pair of spread wings amid clouds and rays; coins or medals and laurel wreaths fall from it onto a heap of books (one lying open to show a crescent and a full disc), a celestial globe on its stand, a telescope, a quadrant-like instrument, a cross-staff, a compass rose and other instruments.

- Lettering: none seen on the vignette, its banners, books or instruments. The faces of the coins or medals were not resolved.

Diagram. An engraved headpiece across the upper third of the page. At top centre, a glory of rays breaking through clouds holds the divine name in Hebrew letters. Choirs of winged angels sit on banks of cloud to either side: those on the left sing from open books, those on the right play a lute, a large bowed string instrument and other instruments. Small winged heads appear among the clouds.

- Glory (top centre): יהוה [Hebrew: YHWH, the divine name], four letters, with a vowel point under the third letter whose form was not resolved.
- No other lettering on the engraving.

To the Kind Reader, Greeting [Benevolo LECTORI S.]

The mind and will of man must certainly be occupied at all times in declaring the glory of God, in searching out the truth, and in increasing the common good. For just as all things in the whole universe were founded for the sake of the human race, so the human race in its turn was created solely for the sake of God: so that it may praise and celebrate for ever the Parent and Founder of all things and of itself, and acknowledge with its whole heart, magnify, and extol with all its strength His admirable power, ineffable magnificence, and goodness, with which He fills the entire world. In this the most holy Patriarchs and all the Prophets carry the torch before us most beautifully; and so too we have a truly great admonisher and spur in King David, interpreter of the Divine Mind, who rouses himself and all of us with these words: BLESS JEHOVAH, O MY SOUL; PRAISE, CELEBRATE HIS NAME, ALL NATIONS, ALL

PEOPLES; SING, MAKE MUSIC TO HIM, SPEAK OF ALL HIS WONDERS; LET EVERY SPIRIT PRAISE THE LORD.

For indeed, whenever we look at even the smallest works of Nature met with anywhere on the globe — whether the minerals in its bowels, the plants and animals on its surface, or finally the meteors in its atmosphere, of whatever kind they may be — and weigh them a little more deeply, the omnipotence, infinite wisdom, and incomprehensible providence of the Divine Majesty shine out clearer than daylight. More than that, all these things give us occasion, and kindle in us the ardour, to proclaim with a most grateful mind the glory, honour, and power of the supreme Maker of things. But above all, if there is anything that more strongly fires the minds of good men and drives them to pour out and render due praises and suppliant thanks to God Most High, it is the sight and contemplation of the vast Celestial Machine. For THE HEAVENS DECLARE THE GLORY OF GOD, AND THE FIRMAMENT PROCLAIMS THE WORK OF HIS HANDS. In the firmament the magnificent Founder of things displays the spectacles of His immense wisdom and His unspeakable works — indeed, miracles for the human senses to wonder at without stint, and equally to search into. So many stupendous and vast bodies present themselves there: not only the Sun, the fountain of light, the Moon, the planets, and the other innumerable fixed stars, as ordinary and eternal bodies, but also extraordinary ones, sometimes temporary too, that come forth into our view, such as new stars and comets. The more rarely these are brought forth from the abyss of Nature and set out before us on high, the more the Supreme Godhead inflames and stirs all mortals: not only to gaze at them and marvel at them on the surface and from afar, along with the common people, but — as befits men especially who are wise somewhat above the common measure, and more capable than others of these sublime things — to look into those hidden secrets and mysteries rather more deeply, and indeed as if at close quarters, with sufficient and suitable instruments applied for the purpose, and to investigate them further. And this with the end, namely, that not only they themselves the unspeak- able works of Jehovah and His mighty deeds more and more, and extol them, but may also rouse others, and indeed even late posterity, and lead them by example to pursue similar things and gradually to search them out more intimately. In this way the most abstruse treasury of celestial things may become more thoroughly known to the whole world; the good arts and sciences, the sidereal ones above all (which God, Best and Greatest, wills no less to be increased and adorned step by step), may take greater growth day by day; and the whole Earth — recognising the eternal Providence, even from the wonderful face, tail, and size of the adventitious bodies too, and above all from their motion, by far the most admirable and the most varied, through that hidden symmetry and unsearchable harmony, however much it is known only in part — may rise up for ever to the admiration, love, and praise of the Supreme Godhead.

Since this is so, and since it falls to everyone to do and pursue this vigorously, according to the measure granted by God, we certainly thought it our part as

well — above all since I have felt in my mind, from my very youth (which I attribute to the Divine Benevolence), an ardour to attempt this and to undertake Uranian contemplations — to weigh and search out, as far as the strength of my ability allows, among the other ethereal bodies, the nature, affections, and properties of the hairy stars in particular. But I willingly grant, even without anyone's reminding me, that this matter of comets is, if any among other things and questions is, extremely difficult, most obscure, and most intricate. Very many philosophers, ancient as well as more recent, have debated it keenly, indeed beyond what can be said; yet even after so many centuries it has not been thoroughly discussed up to now, still less decided, so much so that it remains in doubt even among the greatest of philosophers. Nevertheless I persevered steadily in my purpose (however well I knew the weak powers of my ability, and acknowledged that I am in no way to be compared with those most famous and most learned men who long ago attempted this matter of hairy stars), and I by no means allowed myself to be torn away from it by these difficulties, being firmly persua- ded that in the investigation of Nature one must not lose heart at once; next, that we have by no means been placed by God in this theatre of the world in vain; and further, that the person who has hoped the truth can be found contributes most to discovering it and to advancing the truth of the sciences — as Seneca holds (*Natural Questions* [Natural. Quæſt.], Book 6, Chapter 5). Added to this is the fact that, as we have just touched on, it falls to us to devote ourselves with our whole mind, as far as we can, to inquiring into the truth and passing it on faithfully to posterity. Therefore, although the matter is exposed to very many difficulties, is especially arduous, and appears to require much labour, none of this should deter us in the least. Rather, we must undertake the matter with all the greater desire, zeal, labour, and constancy, trusting entirely in God that He will most kindly grant His grace for carrying out such a praiseworthy endeavour — one that serves the glory of His Divine Name, and truth and the common good — and for bringing it out into the light. In this way, even if not everything can be completed fully in every part, at least some things may be added to what has so far been found and detected, and be worked out somewhat more diligently. For Nature, according to that saying of the Roman philosopher, does not hand over her sacred things all at once: she willed nothing great to come about quickly, but set a difficulty before every finest work, to be overcome at last by labour and practice. Moreover, our minds could be kindled in no small measure to take up and carry through this business the more eagerly by what the most wise man just praised pronounced, as if foretelling it, in Book VII, Chapter 25 of the *Natural Questions*: The time will come when our posterity will wonder that we did not know things so plain. There will be someone who will one day show in which regions comets wander, why they travel so far apart from the others, and how large and of what kind they are.

But I would not have you think, friendly Reader, that I credit the powers of my ability with so much, and claim so much for myself, as to believe that I

am the one who has been granted all the faculties and gifts needed to put the final hand, now at last, to that matter, by far the greatest and the most involved. So far indeed is it from the case that this sweetness of vain confidence has ever soothed my mind, that ra- ther I never let myself be persuaded that the day would come when I would take up even some rather slight remarks on this so deeply hidden matter of comets, let alone set them down in writing and send them out to the public.

Several years ago, however, with God's favour, our Selenographic work was brought to its end with favourable success, and at the same time the fairness and goodwill of readers became plain: I understood that those efforts of ours had not displeased them all that much. I therefore judged that this too fell to me — to discharge the promise made in the Preface and the Epilogue of the *Selenographia*, and to put in strenuous effort, as far as my strength allowed, so as to make public, with the best of intentions, what I had so far hunted out privately with the greatest zeal. Accordingly I believed I must go on along that road once attempted, since it is finer even to spend one's life for the public than to pass one's time — than which nothing is more precious — in ignoble torpor.

Strong spurs were added a little later, when at almost that very time, by what was, as it were, a singular fate — namely in the year 1652 — a certain hairy star [Sidus quoddam crinitum] had shone out. At my first sight of it, I confess, I was roused to a remarkable degree to continue tirelessly those celestial observations begun long before. The appearances of comets have indeed for the most part been, as it were, incitements and rousers for observers of the heavens [Uranoſcopis], urging them to cultivate and advance astronomy more successfully. That this is so is not hard to prove from the examples of many most distinguished men, such as Hipparchus, Regiomontanus, Tycho and others. For the first and the last of those I have named, seizing that occasion, were moved to dare a thing presumptuous even for God, if we may speak so — to count out the stars for posterity and to set out the courses of the stars by rule; the middle one, for his part, undertook to establish the method of observing parallaxes. I say nothing of how many notable things, hitherto unknown, have been discovered and explored by many others thanks to the more recent comets. For my part, to confess frankly about myself how the matter stands: even if I do not come into the reckoning of those eminent men, unless the comet had shone out in the year I have mentioned, 1652, I would never by any means have been drawn into that immense and austere labour: measuring the wandering and the fixed stars — not only all the old ones, but many new ones besides — compiling a new catalogue of the fixed stars [Inerrantium Catalogum], and composing this very *Cometography*.

At first I had decided on nothing more than to draw accurate observations of that comet from the sky itself, as far as could be done at that time, so as to investigate more thoroughly its apparent and its true motion, and also its place, size and distance from the Earth. But once I had set my hand to the work and begun the calculation, I saw at once that the labour would not be altogether

fruitless if, at the same time, those various questions met with everywhere among astronomers and philosophers — and, besides, others descending one from another — were thoroughly shaken out, and if the observations of other comets too were subjected to the most exact calculation possible and examined to the bottom. For in that way, I thought, something solid could at last be pronounced and established about the fixed course of comets, their origin and their end [Ortu, & Interitu], and about so many very diverse phenomena and theories. And yet these very things would have deterred me almost on the threshold, had I not taken heart again and again and believed that, with God's help, the matter must be carried through, and that one must go as far as one could reach. In great things, surely, even to have willed is enough.

Having therefore humbly implored divine aid, I undertook, on the occasion both of the comet of the year 1652 and of certain later ones, to compose a universal *Cometography*. With all the zeal I could, I began to describe and explain the whole nature of comets: their place [Sedem], parallaxes, distances, origin and end, likewise the wonderful appearances and properties of their heads and tails, and above all their motion, both apparent and true, which is supremely to be admired. And I did so in such a way that, by proposing a single hypothesis, and that a firm and fitting one, I strove to demon- strate everything and illustrate it with examples; to examine, too, all the phenomena that arise and the questions partly already raised and partly still to be raised; to establish our own view with solid reasons; and briefly to refute the opinions of our opponents. Briefly, I say, because, so that this work should not swell to an excessive bulk, I was always more concerned to go about strengthening our own view than to set about demolishing other people's entirely.

In general, however, we have laboured to this end: that in this philosophical matter we should also philosophize freely and not heed the authority of anyone, whoever he might be — in those matters, that is, where sense, reason and observation evidently proved the contrary. In this we follow the precept of our most illustrious Royal Society and its motto: NULLIUS IN VERBA [on the word of no one]. If everyone, and indeed our posterity too, would set their feet in such tracks, judging that philosophy is not to be cultivated as if handed down by descent [ex traduce], nor that one may rest securely in certain pronouncements and discoveries of the ancients, there is no doubt that the boundaries [pomœria] of the sciences and arts will be advanced to a wonderful degree, that the recesses of things will at last be opened out, and that new marvels, still hidden in the vastness of Nature, will day by day be most happily disclosed — as a most beautiful hope already shines out — and, drawn into the light, will be set before the eyes and the gaze of all.

As for the order of this work, we have followed the one that the nature of the material itself, and of the observations, dictated to us. In the First Book, therefore, we have dealt specifically with the comet of the year 1652 [Anni milleſ. ſexenteſ. quinquageſimi ſecundi]. We subjected its observations to the most rigorous calculation, so that the apparent motion of that comet —

both with respect to its orbit and with respect to the ecliptic and the equator — and the other matters belonging to it might be worked out, and a solid foundation thus laid from which the parallaxes and the remaining matters could be more correctly derived and deduced. In the Second we have shown clearly that both the comet just named and all the others were ethereal. In the Third, on parallaxes in ge- neral, of all comets we have treated, though in a plainer fashion [rudiori tamen Minervâ], and from them we have likewise established that comets move in the highest aether.

In the Fourth, we deal with the parallaxes of the comet of the year 1652, both vertical and horizontal, investigated by a more accurate method. There it is shown not only by what route — and that a very diverse one — they are precisely worked out, and on what supports, as it were, they rest, but also how laborious and subtle a business it is if anyone tries to follow out each step accurately. To this were added very many axioms, supremely necessary for carrying out that method correctly, with the procedure shown at the same time and followed throughout for the comet of 1652. And since the matter is most intricate and very difficult, I thought it necessary also to present almost the entire calculation, and to attach to each example its own diagram [Schema] for greater clarity — especially since, so far as I know, parallaxes have not until now been investigated by this new method, let alone sufficiently demonstrated by geometrical calculation.

In the Fifth, it is proved from the distances of comets from the Earth that they are not sublunary but celestial. In the Sixth, we deal with the apparent and the true size of the head and of the tail, and likewise with the light and colour both of the comet of 1652 and of others whose observations reached our hands; at the same time all the phenomena and questions bearing on this subject are investigated and discussed. In the Seventh, we have discussed the origin of comets, their genuine matter, form, properties and end, and have set out our view on all of these at length. In the Eighth, we have treated the tails of comets and their various phenomena, colour, light and wonderful appearances, and we have presented them drawn from life and engraved in copper by our own hand, like all the other figures. In the Ninth, the motion of comets is explained at length: where, namely, does it arise? Does it proceed in a circle, or in a straight line, or in a conic one? Is it equal or unequal at all times? Further, what increases and decreases of speed and slowness does it undergo? — and a great many other matters of this kind. By the same labour, however, our hypothesis too is explained at length, and it is clearly shown that by its means all comets can be conveniently accounted for [sustineri], and every inconsistency met most correctly — as we have gone on to elucidate and establish there by a more accurate calculation, by examples, and by a great many figures.

For the rest: while I was labouring on these things, other highly notable comets besides came my way, and I thought it not beside the point to search out their observations with equal diligence — above all because this was very much in keeping with our plan, and it seemed that much light would accrue

to this work from it. Accordingly, although I had firmly resolved to crown the whole work with the Ninth Book, judging that in the preceding books almost all the material had been examined amply enough, unless my opinion deceives me, I nevertheless promptly changed my mind and added three further books.

The Tenth, indeed, for this reason: that I might also investigate the comet of the year 1661 more exactly and weigh each of its particulars, since, using very large instruments, I had successfully collected sound observations, highly useful both for explaining any phenomena whatever and for confirming our hypothesis. In the Eleventh Book, then, are set out the matters concerning the two later comets that remained after the publication of our *Prodromus* and *Mantissa*: namely, the genuine hypotheses and the parallaxes of these comets. Above all, we have shown at very great length, from a great many observations, and those by no means trivial, presented in the *Mantissa*, that our theory can be established no less for these last three hairy stars [Sideribus crinitis], consistently in every respect, and that no phenomenon whatever is met with in them that does not likewise obey our laws and avoid all absurdities. Finally, in the Twelfth Book I have comprised the history of all comets, from the creation of the world down to these our times, whichever were recorded by historians, chronologers and astronomers. Since I judged that it would be no useless labour if, of each and every co- mets, their remarks [Animadversiones] — astronomical ones, that is — were gathered as it were into a single bundle, with all the rest, which are not at all to the point, entirely discarded. For it is perfectly clear what examples and various observations contribute to the understanding of things, especially if they have been carried out and recorded accurately. But how meagre are the observations we have of past comets — apart from a very few more recent ones gathered in this and the previous century — the history of comets itself clearly proves. If our predecessors had handed down to us more, and more certain, information on this subject, there is no doubt that this history too would have been made far richer. But what has so far been neglected in this area through the carelessness of others must be repaired in the course of time by our own care and zeal and by that of posterity; and we wish with all our heart that this may come about and succeed happily.

You have, then, a succinct outline and, as it were, an idea of this whole cometographical work. If you want more, and more particular, detail, my reader, you may, if it is not burdensome to you, either read the whole volume through or at least run through it with a passing eye. I have no doubt at all that you will recognize that, although on this most profound subject I could not satisfy everyone — much less bring the matter to the point where nothing whatever is left over for others — I have nevertheless at least laboured toward that end as far as the feeble powers of my mind allowed; that I have left nothing untried, and have spared no labour, however extremely tedious, so as to track down the truth by every means. And if I have not yet entirely found and uncovered it, as could hardly be done so easily in so arduous a matter, I shall hand the torch, with entire equanimity, to you and to our successors, for

something more excellent and more solid to be worked out and produced. For one age is not enough for the investigation of such great mysteries. We indeed hold the most certain hope that at length, some day, either you or others — men, that is, of weightier learning and loftier genius — more closely than has hitherto been done by our- selves, will take aim at the mark — above all since in this our age supreme kings and princes, a thing in which the whole learned world greatly rejoices and glories, not only love distinguished men devoted above all to the advancement of natural science and bestow every honour on them, but also, by their singular grace and clemency, most kindly spur them on and wonderfully kindle their spirits.

For my part, I am fully content with the testimony of my conscience that in this little work I too have attempted something here, and have sought to discover in this arduous business of comets certain things which, as I judged, bear on the glory and honour of the Creator of the ages [Conditoris ævi], and on bringing the truth to light and advancing the public good.

Of your fairness and kindness, kind reader, I promise myself with certainty that you will value at their proper worth, as is fitting, these efforts of ours, such as they are: undertaken in a good spirit, and carried through with the greatest labour, with no small wasting of my bodily strength, on account both of the very extensive calculation and of the very many figures engraved in copper by my own hand. But if you find that I have now and then strayed, as humans do, and miss certain things in some places, I trust that you will readily forgive it to the slenderness of my talent and to the manifold and very heavy occupations, public as well as private, by which I am overwhelmed almost day and night.

As for the rest [Quod ſuperſt] [recte: Quod ſupereſt], I gladly and reverently submit everything contained in this work to the judgement of all who both love and understand the truth, and above all to the most wise censure of our most illustrious Royal Society. If I see that there is someone able to bring forward a more fitting hypothesis, supported by more solid and more evident reasons and demonstrations, and to overturn ours completely, I shall hand him the grass [herbam porrigam — that is, concede victory] not unwillingly; indeed, I shall gladly congratulate myself and my victor alike. For I never cling so stubbornly either to my own opinion or to that of any master, of whatever authority he may be, that to a truer view — as anyone devoted to wisdom, and to whom petty vainglory is ab- horrent, ought — I would not most gladly yield. Let truth therefore prevail, let virtue prevail (to make my own the words that the most learned Jeorgii Joachimi Rhetici [Georg Joachim Rheticus] uses in his *Narratio prima* to Schonerum [Johannes Schöner]), and let the arts always be held in their due honour, so that every good practitioner of his art may bring to light whatever is of use, and defend it in such a way that he may be seen to have sought the truth. Farewell.

[Privilege]

Imperial Privilege [Privilegium Cæſareum.]

We, Leopold, by the favour of divine clemency elected Roman Emperor, ever August, and King of Germany, Hungary, Bohemia, Dalmatia, Croatia, Slavonia, etc., Archduke of Austria, Duke of Burgundy, Styria, Carinthia, Carniola and Württemberg, Count of Tyrol, etc., acknowledge and make known to all by the tenor of these presents:

Our honourable, faithful and sincerely beloved Johannes Hevelius, consul in the Old Town of Danzig, has had it most humbly represented to Us that he has not only already published various mathematical works in print, but also has in hand certain further studies [lucubrationes] belonging to the same discipline. By these he hopes that this age of ours, and above all the discipline of astronomy, will be notably enriched, and that all the learned men of the Christian world will be greatly helped; and he wishes to entrust them to a printer of his own to be printed, and to make them public. To this end he has acquired, at his own expense, no ordinary printing equipment. He fears, however, that (as usually happens) other printers too, for the sake of gain, may fraudulently imitate the same books to his great loss, commit them to the press, distribute and sell them, or else disturb him in some way in publishing those works of his with his own type. He has therefore humbly begged Us to deign graciously to protect him with Our Imperial Privilege, by which he would be safeguarded, in the Holy Roman Empire as well and in Our hereditary dominions, against all frauds and disturbances of this kind.

Since We always judge those who apply their distinguished talents to the further advancement of liberal studies and disciplines to be worthy of Our Imperial favour, and have resolved to accede to this petition, as humble as it is fair, We therefore firmly forbid and prohibit each and every printer, bookseller and anyone else whatever who carries on the book trade from presuming to disturb the said Johannes Hevelius in his undertaking. Nor may anyone, for a period of twenty-five years — reckoned, both for the books already published and for those still to be published, from the first day of publication — within the bounds of the Holy Roman Empire and of Our kingdoms and dominions, reprint the books he has published heretofore or will publish hereafter, in similar or any other type or format, wholly or in part; give them to others to be reprinted; or bring in copies printed elsewhere, sell or distribute them, secretly or openly, against the will and without the consent and licence of the said Johannes Hevelius and of his heirs and successors.

If anyone, acting otherwise, dares to violate or transgress this Imperial privilege and prohibition of Ours, We decree that he shall not only be deprived in fact of such books, wrongly reprinted and imported (which the said Hevelius, or his heirs and successors, may claim for themselves wherever they are found, either on their own authority or with the help of the magistrate), but shall also be fined, with all hope of pardon removed, ten marks of pure gold, to be paid in equal shares to Our Imperial treasury and to the party who avenges the fraud and disturbance. Provided, however, that four copies of each book are sent to

Our Imperial Aulic Chancery, and that the tenor or an extract of this present Privilege of Ours is printed at the front of the books to be published hereafter. We therefore command all Our and subjects of the Holy Empire and of Our hereditary kingdoms and dominions, of whatever estate, rank, order, dignity or pre-eminence they may be, ecclesiastical as well as secular, and especially those who, placed in office, administer law and justice either in their own name or in the name and place of their superiors: that they allow no one rashly and with impunity to transgress or violate this Imperial privilege of Ours, but rather see to it that any offenders they discover are punished with the prescribed penalty and pursued by other means, inasmuch as they themselves would not wish to pay the same fine. Witnessed by these letters, signed by Our own hand and secured with Our Imperial seal. Given in Our City of Vienna, 1662 March 6, in the fourth year of Our Roman reign, the seventh of Our Hungarian, and the sixth of Our Bohemian.

Leopold
L. S. [the place of the seal]
Wilderich, Baron von Walderdorff [Wildericus Baro de Walderdorff.]
By the express command of His Sacred Imperial Majesty.
J. Walderode

Royal Privilege [Privilegium Regium.]

We, John Casimir, by the grace of God King of Poland, Grand Duke of Lithuania, Ruthenia [Ruſſiæ], Prussia, Masovia, Samogitia, Livonia, Smolensk and Chernihiv [CZernichoviæq;], and also hereditary King of the Swedes, Goths and Vandals, make known by these Our present letters to each and every person whom it concerns, or may in any way concern:

We have always judged worthy of Our Royal grace and favour those who apply their distinguished talents to the further advancement of the liberal disciplines, and who thereby gain renown both for themselves and for the arts they practise, and moreover bring forth outstanding fruits for the use of common life and benefits for distant posterity; and We consider that to encourage and spur on such men belongs above all to the office of Our Royal Dignity. We have learned, from persons whose good faith is proven to Us and who are able to judge the sublime sciences, that the noble and worshipful Johannes Hevelius, consul of Our Old Town of Danzig, faithfully beloved by Us, has for a good many years now cultivated the mathematical disciplines, above all astronomy, with excellent talent, exact judgement, untiring labour and, finally, the greatest expense. He has done so to such effect that he has not only collected countless new and rare observations and, by publishing a number of most accurate writings based on them, has so far enlarged the broad estates [latifundia] of that celestial science, to the highest applause of all the learned in the Christian world; but he also now has in hand works by which this age may be notably adorned, and divine Astronomy brought, as it were, to its perfection, with a splendid yield that will flow from it to other excellent

matters and to the common use of life. This he does above all by means of his machines and astronomical instruments and the exquisite mathematical apparatus belonging to them, the equal of which Europe does not have at this time, and which We Ourselves, being at Danzig about two years ago with the Most Serene Queen, Our most beloved consort, surveyed graciously with Our own eyes and in admiration.

Moved by all these things, and from Our kindly inclination towards him, We have undertaken to honour the said noble Hevelius with Our Royal commendation for so many excellent endeavours and labours — also for the sake of the commonwealth itself, to which he contributes these things as an ornament — and, although he is sufficiently encouraged in himself, to encourage him further and to defend him with Our patronage. And since We have learned that he wishes to entrust the studies he has in hand to a printer of his own to be printed, and has acquired for this purpose, at his own expense, no ordinary printing equipment, We wish the aforementioned Hevelius and his printer to be protected against the frauds of any persons who might perhaps wish, for the sake of gain, perversely to print the same studies and to imitate them in type.

For this reason, by Our Royal Authority, We prohibit and forbid any printer, bookseller or other person who carries on the book trade to imitate in type, publish, print, or sell when printed elsewhere, the books which the noble Johannes Hevelius has either published heretofore or will publish hereafter, in any type and format whatever, whether whole or any part of them, within the bounds of Our Kingdom and Dominions, for the next twenty-five years, reckoned from the first day of publication, without Hevelius's own, or his heirs' and succes- sors' knowledge and consent — none may dare it — on this added condition, however: that three copies of every book are sent to Our Court. If anyone presumes to transgress and violate this disposition of Ours, it is Our will that he shall not only be deprived of such books, which are to be claimed for the said Johannes Hevelius and his heirs and successors, with the help of the magistrate, wherever they are found, but shall also be fined and punished four hundred Hungarian gold pieces [aureis Vngaricalibus], one half to go to Our Royal revenues and the other half to the same Hevelius or his heirs and successors. We command all courts and offices, and all magistrates whatever established within Our Kingdom and Dominions, ecclesiastical and secular, territorial and municipal [Terreſtribus & Civilibus], not to allow anyone to violate or disregard this Privilege of Ours, but to proceed severely against all contraveners whatever according to the foregoing, and to see to it that proceedings are taken against them and their temerity restrained by every means — as, out of regard for Our favour and the duty of their offices, they will not do otherwise. In witness of this We have ordered these presents, signed by Our hand, to be secured with the Seal of the Kingdom. Given at Warsaw, 1662 February 3, in the 13th year of Our reign in Poland and the 14th in Sweden.

John Casimir, King [Joannes Caſimirus Rex.]

L. S. [the place of the seal]

Stephanus Hankiewic, Secretary of His Royal Majesty [Secretar. Reg. Majeſtat.]

Index of the Books and Order of the Whole Cometographic Work [INDEX LIBRORUM Atque Series totius Operis COMETOGRAPHICI.]

Book One [LIBER PRIMUS]

It contains the observations of the comet of 1652, and the whole calculation by which its apparent motion was investigated, both with respect to its orbit and with respect to the ecliptic and the equator, with a view to the parallaxes and the other matters to be deduced from it.

Book Two [LIBER SECUNDUS,]

It proves from its motion that the comet was ethereal.

Book Three [LIBER TERTIUS,]

It treats of the parallaxes, derived by a cruder method, that follow when the seat of comets is posited in different regions of the air, and it shows that comets move in the highest ether.

Book Four [LIBER QUARTUS,]

It presents the genuine parallaxes of the comet of 1652, vertical as well as horizontal, and also sets out a more accurate method, by which they were determined in this comet and by which they can be investigated exactly in the other comets too.

Book Five [LIBER QUINTUS,]

It discusses the true place of the comet and its distances from the Earth, and proves conclusively that comets are not sublunary but celestial.

Book Six [LIBER SEXTUS,]

It discloses the apparent and the true size of the head and the tail, and the light and colour, both of the comet of the year 1652 and of certain other hairy stars; and it searches out, examines and elucidates all their phenomena, discussing at the same time a great many questions on the same subject.

Book Seven [LIBER SEPTIMUS,]

It sets out at length the author's opinion on the origin, the true matter, the form, the properties and the passing away of the comet of the year 1652 as well as of all other comets.

Book Eight [LIBER OCTAVUS,]

It treats of the tails of comets and of their various phenomena, colour, light and remarkable appearances, and at the same time puts these before the eye, drawn from life.

Book Nine [LIBER NONUS,]

It clearly sets out the motion of comets, both in general and in particular, and the author's whole hypothesis, by which single and fixed hypothesis the course of all comets, the apparent as well as the true, can be successfully defended and preserved, as is amply confirmed there by a great many examples and diagrams.

Book Ten [LIBER DECIMUS,]

It comprises the description of the comet of 1661, and its observations themselves, not only bare but also worked out, as well as its theory.

Book Eleven [LIBER UNDECIMUS,]

It sets the theory of the two more recent comets, namely those of the years 1664 and 1665, quite clearly before the eyes, and fully explains and demonstrates what remained to be said of them after the *Prodromus* and the *Mantissa*.

Book Twelve [LIBER DUODECIMUS,]

It contains the history of all comets, as many as have ever been recorded and observed up to the present by historians, philosophers and astronomers, with the author's notes and remarks.

Annexed to this Twelfth Book is a table presenting all the comets and their principal phenomena in order.

Catalogue of the Authors Mentioned in This Work [Catalogus Auctorum, quorum mentio fit in hoc Opere.]

A.

- Benedictus Accoltus
- Achilles
- Acosta
- Paulus Aemilius
- Aeschylus
- Aimonius
- Albertus, Abbot of Stade
- Albertus Magnus

[Two blocks, left and right of a vertical rule, each line of the page carrying one row of each; no column heads are printed. "Figure" stands only on the rows where the page prints "Figura". In the right block from AA onward the second letter is printed as a small capital.]

To the Man Illustrious in Fame and Most Distinguished in Dignity, Master Johannes Hevelius, Consul of the Renowned Commonwealth of Danzig [VIRO FAMA ILLUSTRI, DIGNITATE AMPLIS. DN. JOH. HEVELIO, INCLYTÆ REIP. GED. CONSULI.]

They say that horrifying Comets portend dire things, blazing portentously with baleful manes. From this they at once announce famine and plagues of every kind, and prophesy wars about to weigh upon so many peoples. But let timid Minds fear the harmless Stars, and tremble, captive to ignorant credulity. Whoever turns the pages of Hevelius's illustrious Monuments, and the Books the ages will carry with mindful praise, will not, indeed, come away without a sacred awe, nor fail, in reverence, to be astonished at the noble Work; yet all the while he will feel his breast touched by no fear to make it tremble, and by no stunned dread. Rather, he will marvel in his mind at the Arts of the stars, and at so many hidden things of the star-bearing Pole laid open; and, having roamed far and wide along the paths of vast Olympus, he will gaze on the silent torches with their flickering fire. Above all he will long to have the Comets, blazing with varied hair, set before his own eyes. Where they take their origin; what feeds such great tresses; by what track their sudden journey is accomplished; and the things that trouble the minds of anxious mortals: all this, brought to light by fortunate diligence, he will read. O breast teeming with Heaven! into which the Cynthian father himself has poured whatever light he had. The eager World applauds these heavenly studies, and looks up to the lofty undertakings of the ethereal Man. They celebrate the divine Acumen of his skilful Genius, to which the starry Hall unfolds its recesses.

They praise the Artist's exact engravings of the Heavens, and all that he has set down in gleaming copper, and his Hand; and whatever, bought with

wakeful care through so many nights, a learned age longed to see come to light. All this presents itself to Your Genius, most great Louis, in reverence for the summit of the Bourbon Throne. Olympus was showing You worthy of so great a gift, Olympus, which delights to move propitiously at Your nod. Your Favour, of course, has long been rousing the Arts that deserve it, and bids them hope for sure Rewards. Mars lifts his laurelled Head in honour, because You shine, fearsome, in Your ancestral Arms, no more than loyal Apollo boasts that You, who revive the gentle Muses with Your calm Light, are his own glory. Hail to Your spirit! Hail, most sacred King, to these prayers! By this path of Heaven the serene Summit is sought! This Virtue once bore Alcides [Hercules] into the shining Stars, and gave such great increase of Praise! He, indeed, was able to overcome the Lion of Nemea: yet he was no less the Leader of the Muses [Aonidum Dux]. And who would have known that he laid low the Nemean Lion, had Calliope not celebrated the splendid deed? He is said, too, to have borne Heaven on his unconquered neck, and to have set the Poles upon his own head. You too, surely, August One, such rare Glory will await; and already the fates are preparing this honour for You. This same Right Hand, which now, devoted, sets forth the Comets alone, relying on Your Auspices, destines for You the immense Orbs of the whole Heaven, and all the Stars, arranged in their own regions. O may the Aether favour these great Undertakings, and rejoice that it is forthwith shaped by this Hand!

Written at Danzig [Scribeb. Gedani]

Joh. Petr. Titius

Johannes Hevelius, Cometography, Book One [JOHANNIS HEVELII COMETOGRAPHIÆ LIBER PRIMUS.]

Section I. General Description of the Comet of the Year 1652 [SECTIO I. Generalis Cometæ anni 1652. deſcriptio.]

In the year of the Christian era 1652, on Friday, December 20 by the Gregorian style, on the evening just before the winter solstice, at about 6^h, with a very clear sky inviting me, I climbed to my astronomical observatory with two companions well practised in observing the stars. My intention was to take, as carefully as I could, various altitudes and azimuths of the fixed stars with our large brass azimuthal instrument [inſtrumento magno noſtro Orichalcico Azimuthali], both in order to work out afterwards the refractions of our horizon at Danzig, and at the same time to examine Tycho Brahe's table of refraction. So I set about this work, and was already observing some altitudes of Palilicium [Aldebaran] and of Canis Minor, which stood around Subsolanus and Hypeurus, when — behold — an unusual and very rare phenomenon, bearing the appearance of a comet, presented itself to our view towards Vulturnus, a little before 7^h, with Palilicium at an altitude of $34^\circ\ 25'\ 30''$ and Orion rising above the horizon. I had been thinking of no such thing, much less expecting it.

[Margin: The comet's first appearance.]

It stood, in fact, not far from the star otherwise named Regel [Rigel], that is, the left foot of Orion, though a little higher and to the right, near a small star of the fifth magnitude in Eridanus that follows two others. Thus at that time it formed a roughly equilateral triangle with the said star Rigel, of the first rank, and with the star of the third magnitude in Eridanus above Orion's foot; and with the two upper stars of the fourth magnitude in Eridanus it made an almost straight line.

[Margin: The comet's position.]

The head was round and of unusual size, appearing hardly any smaller than the full Moon. It stretched out a remarkable and long tail, or beard, of six or seven degrees, towards Orion's belt and towards Subsolanus — turned away, that is, from the Sun — through the said star above Orion's foot, which shone very brightly within it, as far as very nearly the star in the hilt of the sword. The light of the head, however, was pale, and

[Margin: Size and shape.]

partly blunted and less bright, and it looked like the Moon covered by a very thin cloud. The tail had a similar light, though weaker still and thinner, ending in a very fine point.

All of us, therefore, were astonished and struck by a kind of silent amazement. When we first noticed this new spectacle, each asked the other what it could mean there, and what sort of thing it was. My observers, indeed, judged it to be plainly a meteor, some apparition [phaſma] of no importance; I, however, thought it something of a wonderful and celestial nature, and scarcely a meteor. So I had decided to break off the remaining observations of the fixed stars entirely and to devote myself solely to this phenomenon. But my collaborators, since they wholly rejected our opinion and presumed nothing of the kind, pressed me so keenly to continue with energy the work we had undertaken, the sky being so favourable, that I let myself be persuaded, for their sake, to set the phenomenon aside for the time being and to go on attending to the altitudes (and indeed a great many altitudes, 40 in number, of Palilicium and Canis Minor as well as of Pollux and Sirius, were taken at that time); to measure only some distances of the phenomenon and of certain stars, and those with nothing but a smaller radius, because the sextant was not to hand; and to draw with the greatest care its position with respect to the whole constellation of Orion, and its true appearance, as can be seen in the following figure — against every eventuality, since my mind foreboded, and urged on me, that this was something singular and almost divine.

[Margin: Why the comet was not observed accurately on the first day of its appearance.]

At 9^{h} 52^{m} by our clocks, however, with Sirius at an altitude of 11° 40′, I noticed that the phenomenon was moving fairly fast, by its own motion, upward — that is, towards Orion's shield — (although at the same time, by the common motion, it was tending towards its setting), while still remaining in the same straight line with those two stars in Eridanus mentioned above.

Since it now formed a roughly isosceles triangle with Rigel and with the star in Eridanus above Orion's foot, I was made more certain in my opinion. And so, for the reasons given, and also because it constantly cast its tail turned away from the Sun, I did not hesitate to declare boldly that it was a comet and a plainly ethereal body — notwithstanding the argument that it did not spread its light as vividly and brightly as most comets do. I added, moreover, that I already sensed that this phenomenon was directing its course towards the Pleiades and Perseus, and that on the following day it would no longer shine in the place where it shone today, but would appear around Orion's shield. To some, indeed, this may seem to have been pronounced by me too rashly and hastily, and from a single observation at that; but from the straight line along which it continually advanced, from the fast proper motion by which it was carried, and from other circumstances, I could safely predict it.

[Margin: The first, rougher observation.]

[Margin: The comet was carried by its own motion towards the Pleiades.]

I was therefore fully resolved to examine at once, rather more carefully and with larger instruments, both its altitudes and azimuths, together with its transit through the meridian, and its distances from various fixed stars; but I was disappointed in this hope. For clouds, fairly thick, with the Africus blowing, snatched from us the sight of that body (which I certainly regretted all the more, in that, right at the very beginning of its appearance — as I had indeed intended, and as I could also have done excellently, given the clearness of the sky — that phenomenon

I had measured the less) — so that on that first day it was granted us to obtain nothing more than what has been described.

Whether this comet had first risen on this very day, or had appeared on our horizon somewhat earlier, was not at all established at the time. I hold it more certain than certain, however, that on December 16, when I was likewise investigating the refractions by means of the fixed stars from 7^h in the evening until 12^h at night, there was nothing of it at all; nor on the 17th, although the sky was perfectly clear. The 18th and 19th, on the other hand, were completely cloudy, so that I observed nothing whatever. Yet I suspect from its proper motion that the comet could have been seen on our horizon on the 19th, and perhaps even on the 18th, close to the horizon itself; we, however, as we said, first caught sight of it on the 20th.

[Margin: On December 16 and 17 the comet had not yet shone on our horizon.]

[Margin: On what day it first shone at Danzig.]

On the following days, the 21st and 22nd, although I was fully ready to search out this new portent, nothing could be detected, because the sky was completely overcast.

On the 23rd, however, when this phenomenon shone again, I began with every effort to measure its position with quadrants and sextants, as the observations themselves, both of this day and of the following days, amply testify. We

found that this phenomenon had covered a large space by its proper motion, ascending towards Circius or Favonius, and had passed over the equator; it stood, however, a little below Aldebaran and the Pleiades, at a southern latitude of one or two degrees, forming a roughly obtuse-angled scalene triangle. Its tail it stretched out towards about the northern eye of Taurus, pyramidal in the same way as before. Indeed, just as it had been carried with very swift motion during the three preceding days, so, conversely, it was much diminished, both in the size of its body and in the length of its beard.

[Margin: Observation made on the 23rd.]

On December 24 this phenomenon — or rather comet (for it is rightly so called, by reason both of its motion and of its parallax, as well as of its other appearances) — had acquired a northern latitude, and was very close to the Pleiades on their eastern side.

[Margin: Observation of the 24th.]

On the 25th, in turn, no clear sky shone on our horizon. But on the 26th it had climbed higher and higher, forming an almost straight line with the two stars in the left foot of Perseus, except that it seemed to incline a little more towards Aquilo; its distance from the more westerly of them was nearly equal to the distance that the said stars always keep from each other. On the 27th we saw the comet removed a notable distance from these stars in Perseus' foot, gradually heading upward towards the head of Medusa, otherwise Algol. On the 28th it had come closer and closer to the bright star of Medusa, so that on the 29th, at about 4^{h} in the morning, it described an equilateral triangle with the two brighter stars in Medusa's head.

[Margin: The comet formed a straight line with the two stars in Perseus' left foot.]

On the morning of December 30 it made a very close conjunction with the bright star of Medusa, yet in such a way that it stood a little higher, as if hanging over the star. On the morning of the 31st it stood off at a nearly equal interval from Algol and from Perseus' left arm. On January 1 [Calendis Januarii], opening the year of the Christian era 1653, already nearer to that star in the left arm, it appeared, forming an almost right-angled triangle with this star and the bright star of Medusa. On the 2nd, 3rd and 4th it gradually directed its course towards Perseus' left shoulder, yet keeping continually and most strictly to its great circle. On the 5th and 6th the air, filled with very dense murk, shut off from us the view of the phenomenon and of the whole sky. On the 7th it hung very close over Perseus' left shoulder, standing off from the star, on its northern side, by scarcely the space of one diameter. By January 8, heading towards Cassiopeia, it had left the said star somewhat further behind.

[Margin: Conjunction of the comet and the bright star of Medusa.]

Up to this point I not only saw the comet very well with the naked eye, although it had diminished greatly day by day; I also examined, with the utmost and untiring application, spending whole nights mostly without sleep, a great many of its distances from various fixed stars, as well as its altitudes together

with azimuths. For this I used exquisite instruments of proper size, skilfully made of solid metal — above all a sextant, as well as a very large azimuthal quadrant showing single minutes and seconds by tens — and noted at the same time the true time, corrected with the greatest care by the altitudes of other stars. In this way, with God's help, I obtained for the public good a great many most exquisite observations (as may be seen below).

[Margin: Up to when the comet was observed with the naked eye.]

With the Moon waxing and shining, however, on the 9th and 10th, the comet could not be seen with the naked eye, although I strained every nerve at it. Yet on the morning of January 10, with the Moon sinking to its setting, towards Corus, I detected it with the telescope, although in a rather low position and notwithstanding certain exhalations. Afterwards, however, because the Moon was filled with nearly full light, because of the comet's own lower northern position, and because the sky was very often cloudy, nothing more whatever was observed of it by me; and I am fully convinced that not even a trace of it was noticed by others elsewhere.

From the comet's proper motion, therefore, it is clearly evident that it advanced in longitude against the order of the signs, and passed over the equator and the ecliptic at a certain angle of inclination; moreover, that it acquired a large northern latitude; and also — which is well worth noting — that from the first to the last limit of its appearance it traversed at least 65° on a great circle, with a constant and most regular motion. And although at the beginning its motion was much faster, and towards the end slower, it nevertheless always decreased daily in due proportion. In the same way, along with the proper motion itself, the comet diminished from day to day in the size of its head and the length of its tail, as well as in the light and brightness of both.

[Margin: What kind of motion it had.]

These are the things that I gladly wished to relate, briefly and in general, about this phenomenon's first rising and its course, until it withdrew entirely from our sight. More, and more particular, matters will become clear from what follows: namely, how great the comet's daily proper motion was on any given day, not only in its own orbit but also in longitude and latitude; and also how great its parallax was at every time, its true distance from the earth, and the size of its body, together with other matters pertaining to this, as pleasant as they are necessary to know, which are to be drawn from the very sources of the observations and demonstrated by geometrical calculation.

Section II. Observations of the Comet made with the greatest care at Danzig, from 1652 December 20 to 1653 January 8 [SECTIO II. Obſervationes Cometæ Dantiſci Anno 1652, à die 20 Decembris ad diem 8 Januarii usq;, anno 1653, ſummâ curâ peractâ.]

Now that a general description of the comet has been given, it follows that I should present the observations themselves, together with a number of diagrams

[schematismi] carefully drawn at the same time. So that you may be the less confused, my dear lover of astronomy, and so that each item may be set out more briefly, I have entered all the observations in definite tables. Their first column gives the time as noted by the mechanical clock [artificiale horologium]; the second, the altitudes and the versed shadows [umbras verſas], if any were observed; the third, the azimuths of the fixed stars and of the comet; the fourth, the time corrected from the altitudes and azimuths; while the fifth gives the various distances of the comet and the fixed stars (and also other matters most worth noting): both how great they were at any given time, and with which instruments they were obtained. I would have you note, however, that I measured the comet with several instruments.

First, namely, with a certain radius [Radius] about 4 or 5 feet long. This was not because I set much store by it, but because at times, with clouds flying past, no other instrument could serve us at all. Besides, with its help a single observer, alone, is able to take distances; and the matter is dispatched much more quickly, and yet accurately enough, provided due care is applied. Add that the remaining observations, made with sextants, always deserve greater trust if they have also been checked with some radius: for in that way all errors, if any have been committed (as indeed happens at times), are recognized with no trouble.

[Margin: With which instruments the comet was observed?]

Second, with an exquisite brass sextant, accurately divided into single minutes, indeed into half-minutes and their quarters. Because of its moderate size it could conveniently be used at that time in our Uranian observatory [ſpeculâ noſtrâ Uranicâ], together with other instruments.

Third, with our large azimuthal quadrant as well, with which all the altitudes and azimuths of the comet and of the fixed stars were always investigated with the greatest diligence, whenever the clearness of the sky allowed.

Moreover, to the observations themselves we have added special drawings of the phenomenon. In these one sees clearly not only the true position of the comet with respect to the neighbouring stars, but also its genuine shape, both of the head and of the tail, as well as the region and the stars towards which the tail stretched. This is shown best of all in this first observation, made around the comet's first appearance.

At about half past six the comet first shone on us at *c*, extending its tail through *e*, the small star that follows two others (which, because of the smallness of its body and the nearness of the comet, could not be seen at that time), and

[Margin: The earlier observation of the comet.]

the small star *b* above Orion's foot in Eridanus, roughly towards *h*, the uppermost star of the belt. At that time it formed a nearly equilateral triangle with Rigel and with the said star above Orion's foot. The distance between the comet and Rigel was found with the radius to be 3° 7′; between the comet and the star *b*, 3° 25′; and the distance between the fixed stars themselves was 3° 33′.

At 9^h 52^m, however, the comet had already taken up a somewhat higher place, namely *d*; and so that nearer little star also shone out brightly. The tail, though, still passed through the star of Orion's foot in Eridanus, almost as far as the star *f* in the hilt of the sword, towards the middle star of the belt. At that time the comet no longer formed an equilateral triangle but an isosceles one, as we said more fully in the general description of this comet on p. 2, and as can also be seen clearly from the accompanying drawing.

[Margin: The later observation of the comet.]

Diagram. An engraved star chart, framed, filling the lower part of the page. It shows the constellation figure of Orion — head, raised arm, mantle and lion-skin — stippled over its stars, which are drawn as six- and eight-pointed asterisks. At lower right the comet is drawn twice, each time as a bristling round head with a tail; the tail of the upper head runs up and to the left past the belt. Every label printed on the engraving is listed below; none was left unread, though one letter is uncertain.

- ORION. (upper left, over the raised arm): "Orion."
- Prima Cometæ apparitio / Anno 1652. Die 20 Dec. (left, mid-height): "First appearance of the comet, in the year 1652, on December 20."
- [?] (above a large star at the top of the belt): an engraved letter read as either *h* or *b*.
- g (beside the star below it, in the belt)
- f (beside a star on the mantle, right of the belt)
- b (above a star on the comet's tail)
- i (right of a small star at right)
- d (above the upper comet head)
- Hor. 9 52′ (right of the upper head): "9^h 52^m"
- e (above a small star between the two heads)
- Hor: 6 30′. (right of the lower head): "6^h 30^m"
- c (below the lower head)
- a (above the large star at lower centre)
- Regel. (below that star): "Rigel."
- Autor ſculpſit. (lower right, inside the frame): "Engraved by the author."

Observation II of the Comet, made in the evening of 1652 December 23, new style [Cometæ Obſervatio II. Anno 1652, die 23 Decembr. St. n. veſp. peracta.]

Mechanical clock [Horologiō artificiale.] (h m s)	Altitudes of the fixed stars and of the comet (° ′ ″)	Azimuths of the fixed stars and of the comet (° ′)	Time corrected from the altitudes (h m s)	Distances of the fixed stars and of the comet	Notes [Animadvertenda.]
$5^h\ 37^m\ 50^s$	*Aldebaran.* 27° 31′ 0″	78° 26′ east	$5^h\ 46^m\ 21^s$		
$5^h\ 43^m\ 0^s$	*Comet.* 32° 43′ 0″		$5^h\ 51^m\ 33^s$		The sky on this day was troubled by frequent clouds, so that we could not carry out observations as we wished; nevertheless we wrung out a few, though with the greatest labour. Had the sky been wholly favourable, many more observations would certainly have been obtained.
$7^h\ 13^m\ 0^s$	*Comet.* 44° 28′ east	48° 19′ east	$7^h\ 22^m\ 7^s$		
$9^h\ 20^m\ 0^s$			$9^h\ 29^m\ 51^s$	Distance of the comet from Palilicium, by the radius: 320 to 39 parts, or 7° 0′	
$9^h\ 38^m\ 30^s$	*Right shoulder* 39° 5′ 40″	*of Orion.* 31° 25′ east	$9^h\ 47^m\ 46^s$		
$9^h\ 43^m\ 30^s$			$9^h\ 53^m\ 30^s$	Distance of the comet from Palilicium, by the sextant: 6° 55′, but doubtful	At $11^h\ 15^m$ a straight line from the comet to Aldebaran seemed to pass between two small stars.
$9^h\ 51^m\ 0^s$			$10^h\ 1^m\ 0^s$	Distance of the comet from the right shoulder of Orion: 28° 22′, taken with the sextant	
$9^h\ 54^m\ 0^s$	*Rigel* 26° 24′ 0″		$10^h\ 4^m\ 20^s$		At the same time the diameter of the comet, observed several times with the large azimuthal quadrant, was 26′ or 25′. And although the comet had by now greatly diminished, both in its head and its light and in its tail, it was nevertheless still very conspicuous.
$9^h\ 58^m\ 0^s$	*Rigel* 26° 32′ 45″		$10^h\ 9^m\ 45^s$		
$10^h\ 5^m\ 0^s$			$10^h\ 15^m\ 0^s$		

Mechanical clock [Horologium artificiale.] (h m s)	Altitudes of the fixed stars and of the comet (° ′ ″)	Azimuths of the fixed stars and of the comet (° ′)	Time corrected from the altitudes (h m s)	Distances of the fixed stars and of the comet	Notes [Animadvertenda.]
10h 11m 0s			10h 21m 0s	Distance of the comet from the northern horn of ♉ [Taurus]: 20° 27′ 0″, sextant	
10h 17m 15s			10h 27m 15s	The same distance: 20° 27′ 30″, sextant	
10h 19m 45s			10h 29m 45s	The same distance taken again: 20° 28′ 15″, sextant	The colour of the head was pale, and overlaid with a livid whiteness; the tail, however, was about 5° long, and it stretched towards the northern eye of Taurus, though showing a rather dark lividness and a feeble light.
10h 25m 0s			10h 35m 0s		
10h 28m 0s			10h 38m 0s	Distance of the comet from Rigel: 31° 38′ 0″, sextant, doubtful	
10h 31m 45s	*Procyon.* 33° 23′ 45″	45° 31′ east	10h 41m 44s		
10h 47m 20s	*Comet.* 50° 43′ 15″	31° 20′ west	10h 57m 20s		
11h 18m 0s	*Comet.* 48° 4′ 45″	42° 14′ west	11h 28m 0s		
11h 23m 30s	*Aldebaran.* 47° 34′ 0″ December 24, morning	33° 25′ west	11h 35m 24s		
12h 0m 20s	*Aldebaran.* 44° 24′ 0″	44° 31′ west	12h 8m 51s		
1h 17m 0s	*Comet.* 33° 36′ 0″	75° 9′ west	1h 27m 30s		
1h 33m 45s	*Comet* 30° 53′ 0″	79° 55′ west	1h 44m 15s		

[Six ruled columns as on the page. ”East” and ”west” render the printed *Or.* and *Occ.* A star's name, set in italic above the figures in its cell, is given at the head of the cell. The words ”Die 24. Decembris man.” run across the altitude,

azimuth and corrected-time columns on the page and are given here in the altitude column. The Notes column is not ruled into rows: each of its four paragraphs is placed in the row beside which it begins, and runs down beside the following rows. In the third row the mark *Or.* ("east") stands in the altitude cell as well as in the azimuth cell, as printed.]

Observation III of the Comet, made in the evening of 1652 December 26, new style [Obſervatio Cometæ III. Anno 1652, die 26 Decembris St. n. peracta veſp.]

Mechanical clock [Horologium artificiale.] (h m s)	Altitudes of the fixed stars and of the comet (° ′ ″)	Azimuths of the fixed stars and of the comet (° ′)	Time corrected from the altitudes (h m s)	Distances of the fixed stars and of the comet	Notes [Animadvertenda.]
$8^h\ 43^m\ 45^s$	*Of Palilicium* 48° 7′ east		$8^h\ 26^m\ 52^s$		At about 6 in the evening the comet made an almost straight line with the two fixed stars in the foot of Perseus; yet they were not separated from each other by an entirely equal space. For when the comet was observed more accurately with the naked eye, its centre stood 1/5 less distant from the heel [Calcaneus] than the stars were from each other; so the distance between the comet and the heel was estimated at about 1° 45′, the interval between the heel and the following star of Perseus's left foot being given as 2° 10′.
$8^h\ 53^m\ 15^s$	*Right shoulder* 33° 38′ 45″	*of Orion.* 48° 12′ east	$8^h\ 36^m\ 7^s$		
$9^h\ 5^m\ 0^s$	*Right shoulder* 34° 55′ 15″	*of Orion.*	$8^h\ 48^m\ 10^s$	Distance of the comet from the northern horn of ♉ [Taurus]: 24° 11′ 0″, sextant	
$9^h\ 16^m\ 45^s$	*Same altitude* 36° 10′ 0″		$9^h\ 0^m\ 34^s$	Distance of the comet from Palilicium: 21° 32′ 0″, sextant	

Mechanical clock [Horologium artificiale.] (h m s)	Altitudes of the fixed stars and of the comet (° ′ ″)	Azimuths of the fixed stars and of the comet (° ′)	Time corrected from the altitudes (h m s)	Distances of the fixed stars and of the comet	Notes [Animadvertenda.]
9h 20m 0s			9h 3m 49s	Distance of the comet from Palilicium: 21° 32′ 0″, sextant	
9h 31m 0s	*Left shoulder* 38° 34′ 0″	*of Orion,* doubtful	9h 14m 56s	Distance of the comet from the bright star of ♈ [Aries]: 21° 29′ 0″, sextant	
10h 3m 45s	*Left shoulder* 39° 56′ 45″	*of Orion.* 27° 52′ east	9h 46m 15s		
10h 31m 0s			10h 13m 30s	Distance of the comet from Palilicium: 21° 32′ 0″, sextant	At 8h the comet already appeared somewhat higher with respect to those two stars; but because of the comet's excessive altitude, and because of small clouds passing between, we could not observe its altitudes and azimuths.
11h 3m 30s	*Of Procyon* 35° 13′ 0″		10h 46m 47s		
11h 7m 15s	*Same altitude* 35° 31′ 45″	39° 28′ east	10h 50m 6s		
11h 18m 0s			11h 0m 30s	Distance of the comet from Palilicium: 21° 45′, radius, doubtful	

Mechanical clock [Horologium artificiale.] (h m s)	Altitudes of the fixed stars and of the comet (° ′ ″)	Azimuths of the fixed stars and of the comet (° ′)	Time corrected from the altitudes (h m s)	Distances of the fixed stars and of the comet	Notes [Animadvertenda.]
11h 27m 0s			11h 9m 30s	Distance of the comet from the bright star of ♈: 21° 35′ 0″, radius, doubtful	The comet's body appeared somewhat smaller; nevertheless its diameter, measured with the help of the large quadrant, still came to 24′ — which hardly anyone will believe.
11h 33m 0s	*Of Procyon* 37° 41′, doubtful		11h 15m 21s		
11h 38m 0s			11h 20m 23s	Distance of the comet from Capella: 23° 22′ 0″, radius, doubtful	
11h 45m 0s			11h 27m 25s		Its tail, somewhat shorter, reached to about those two small stars in the foot of Perseus, or rather passed 1/3° above them — at 9h 50m, that is.
11h 47m 0s			11h 29m 23s	Distance of the comet from the leading Pleiad: 9° 57′, radius	
11h 56m 0s	*Comet* 52° 36′ 30″, 764 parts of the versed shadow	71° 22′ west	11h 78m 22s		

[Six ruled columns as on the page, with the same conventions as the table for Observation II. In the first row the mark *Or.* (”east”) stands in the altitude cell and the azimuth cell is empty; in the third row the azimuth cell carries only the words ”of Orion”, with no figures. In the last row the words ”764 part. umb.

versa" ("764 parts of the versed shadow") run under the altitude and azimuth figures across the column rule; they are given here in the altitude cell. The last row's corrected time is printed "11 78 22", with 78 in the minutes place, and is given as printed[1]. The Notes column is not ruled into rows: each of its four paragraphs is placed in the row beside which it begins.]

Observation IV of the Comet, 1652 December 27, morning [Cometæ Obſervatio IV. Anno 1652, die 27 Decembr. man.]

Mechanical clock [Horologium artificiale.] (h m s)	Altitudes of the comet and of the fixed stars (° ′ ″)	Azimuths of the comet and of the fixed stars (h m s)	Time corrected from the altitudes (h m s)	Distances of the comet and of the fixed stars	Notes [Animadvertenda.]
$12^h\ 2^m\ 30^s$	*Comet* 51° 36′ 15″	73° 11′ west	$11^h\ 44^m\ 48^s$		
$12^h\ 6^m\ 0^s$	792 parts of the versed shadow		$11^h\ 48^m$ d	Distance of the comet from the northern horn of Taurus: 24° 35′ 0″, radius	With the sky clear on every side, the comet still appeared with a tail, though a very thin one, about 1½° long. Its head was indeed somewhat paler, but it was of conspicuous size.
$12^h\ 8^m\ 15^s$	*Comet* 50° 44′ 0″; 817½ parts of the versed shadow	74° 54′ west	$11^h\ 50^m\ 31^s$		
$1^h\ 6^m\ 0^s$	*Comet* 42° 40′ 30″; 922, direct shadow	87° 52′ west	$12^h\ 48^m$ 15	doubtful	
$1^h\ 13^m\ 30^s$	*Comet.* 41° 27′ 0″; 883½, direct shadow	89° 37′ west	$12^h\ 55^m\ 45^s$		On this day I made no drawing (for I was short of time); but since the clear sky invited it, I observed the comet with a telescope 12 feet long. What its shape was, however, and what worth recording appeared in it, will be told more fully in Book IV, where we have decided to set out certain things specifically about the shape of its body; and its true appearance will be shown there.

[1] a minutes figure above 59 cannot stand; the reading intended is not evident from the page

Mechanical clock [Horologium artificiale.] (h m s)	Altitudes of the comet and of the fixed stars (° ′ ″)	Azimuths of the comet and of the fixed stars (h m s)	Time corrected from the altitudes (h m s)	Distances of the comet and of the fixed stars	Notes [Animadvertenda.]
1h 26m 0s	*Comet* 39° 53′ 30″; 836, direct shadow	91° 54′ west	1h 8m 15s	doubtful	
1h 42m 30s	*Comet* 37° 27′ 0″; 766, direct shadow	96° 19′ west	1h 24m 45s		
1h 48m 0s			1h 30m 0s	Distance of the comet from the Pleiades: 10° 9′, radius, doubtful	
1h 58m 0s			1h 40m 0s	Distance of the comet from Capella: 23° 23′, radius	
2h 0m 0s			1h 42m 0s	Distance of the comet from Palilicium: 21° 58′, radius, doubtful	
2h 2m 0s	*Of Palilicium* 31° 6′ 0″	72° 42′ west	1h 42m 26s		
2h 5m 0s			1h 46m 0s	Distance of the comet from the northern horn of Taurus: 24° 58′, radius, doubtful	

Mechanical clock [Horologium artificiale.] (h m s)	Altitudes of the comet and of the fixed stars (° ′ ″)	Azimuths of the comet and of the fixed stars (h m s)	Time corrected from the altitudes (h m s)	Distances of the comet and of the fixed stars	Notes [Animadvertenda.]
$2^h\ 25^m\ 0^s$			$2^h\ 6^m\ 0^s$	Distance of the comet from Palilicium: 22° 5′ 30″, sextant	
$2^h\ 29^m\ 0^s$			$2^h\ 10^m\ 0^s$	Distance of the comet from the northern horn of Taurus: 24° 35′ 45″, sextant	
$2^h\ 37^m\ 15^s$	*Right shoulder* 29° 39′ 0″ west	*of Orion.* 57° 4′	$2^h\ 19^m\ 44^s$		

[Six ruled columns as on the page. ”West” renders the printed *Oc.* and *Occ.* A star's name, set in italic above the figures in its cell, is given at the head of the cell; the words ”part. umb. versa” and ”Umb. recta”, set under the altitude figures and running across the rule into the azimuth column, are given in the altitude cell. The first ruled row carries two clock lines, $12^h\ 2^m\ 30^s$ and $12^h\ 6^m\ 0^s$, given here as two rows; the words ”792 part. umb. versa” stand on the second line, under the altitude figures of the first. The heading of the azimuth column carries the unit line ”Ho. Mi. Se.” (hours, minutes, seconds), as printed, although its cells give degrees and minutes; the unit line of the altitude column is printed ”Gr. Mi. See.”. In the rows for $1^h\ 6^m$ and $1^h\ 26^m$ the word *dub.* (”doubtful”) stands alone in the distance column, with no distance. The Notes column is not ruled into rows: each of its two paragraphs is placed in the row beside which it begins.]

Observation V of the Comet, made on 1652 December 27, new style [Cometæ Observatio V. Anno 1652, die 27 Decembris St. n. peracta.]

Mechanical clock [Horologium artificiale.] (h m s)	Altitudes of the fixed stars and of the comet (° ′ ″)	Azimuths of the fixed stars and of the comet (° ′)	Time corrected from the altitudes (h m s)	Distances of the fixed stars and of the comet	Notes [Animadvertenda.]
$4^h\ 59^m\ 30^s$	*Of Palilicium* 22° 24′ 0″	86° 0′ east	$4^h\ 53^m\ 12^s$		
$5^h\ 5^m\ 0^s$	*Of Palilicium* 23° 8′ 0″	84° 52′ east	$4^h\ 58^m\ 15^s$		The comet was indeed decreasing in size, motion and light; yet it remained quite conspicuous. It directed its tail, about 4° long, between the left leg and the two stars in the foot of Perseus. This place lies, as far as could be judged, at 28° 30′ of longitude and 14° 0′ of latitude.
$5^h\ 14^m\ 0^s$	*Of Palilicium* 24° 8′ 0″	83° 38′ east	$5^h\ 7^m\ 5^s$		
$5^h\ 18^m\ 0^s$			$5^h\ 11^m\ 5^s$	The comet and Palilicium under the same vertical circle	
$5^h\ 21^m\ 0^s$	*Comet* 49° 51′ 0″	80° 39′ east	$5^h\ 14^m\ 5^s$		
$5^h\ 26^m\ 0^s$	*Comet* 50° 26′ 30″	79° 58′ east	$5^h\ 19^m\ 1^s$	doubtful	
$5^h\ 31^m\ 0^s$	*Comet* 51° 16′ 0″	78° 55′ east	$5^h\ 23^m\ 58^s$		
$5^h\ 40^m\ 45^s$	*Comet* 52° 24′ 0″	77° 0′ east	$5^h\ 33^m\ 39^s$	doubtful	
$5^h\ 42^m\ 12^s$	*Comet*		$5^h\ 35^m\ 6^s$	Distance between the comet and Capella: 22° 48′, by the sextant	
$5^h\ 45^m\ 16^s$			$5^h\ 38^m\ 10^s$	Distance of the comet from Palilicium: 24° 16′ 30″, sextant	
$5^h\ 47^m\ 0^s$	*Comet* 53° 33′ 30″	75° 14′ east	$5^h\ 40^m\ 48^s$		

Mechanical clock [Horologium artificiale.] (h m s)	Altitudes of the fixed stars and of the comet (° ′ ″)	Azimuths of the fixed stars and of the comet (° ′)	Time corrected from the altitudes (h m s)	Distances of the fixed stars and of the comet	Notes [Animadvertenda.]
$5^h\ 53^m\ 33^s$			$5^h\ 46^m\ 27^s$	Distance of the comet from the bright star of ♈ [Aries]: 21° 27′ 30″, sextant	
$5^h\ 57^m\ 30^s$	*Comet* 55° 6′ 0″	72° 19′ east	$5^h\ 50^m\ 9^s$		
$6^h\ 47^m\ 30^s$	*Right shoulder* 19° 20′ 30″	*of Orion.*	$6^h\ 39^m\ 44^s$		
$6^h\ 49^m\ 45^s$	*Same altitude* 19° 41′ 0″	74° 35′ east	$6^h\ 42^m\ 9^s$		
$6^h\ 54^m\ 0^s$	*Same altitude* 20° 18′ 0″		$6^h\ 46^m\ 3.8^s$		
$11^h\ 34^m\ 0^s$	*Of Palilicium* 46° 49′ 45″	36° 24′ west	$11^h\ 25^m\ 20^s$		
$11^h\ 37^m\ 45^s$	*Of Palilicium* 46° 30′ 30″	37° 27′ west	$11^h\ 29^m\ 1^s$		
$11^h\ 45^m\ 0^s$			$11^h\ 36^m\ 16^s$		
$11^h\ 53^m\ 15^s$	*Comet* 51° 52′ 40″	79° 36′ west	$11^h\ 44^m\ 31^s$		

[Six ruled columns as on the page. ”East” and ”west” render the printed *Or.* and *Oc.* A star's name, set in italic above the figures in its cell, is given at the head of the cell. In the row for $5^h\ 42^m\ 12^s$ the word *Cometæ* stands in the altitude cell with no figures, and the azimuth cell is empty. In the row for $6^h\ 47^m\ 30^s$ the words ”Humer. dext. Orion.” run across the rule into the azimuth cell, which carries no figures. In the row for $6^h\ 54^m$ the seconds of the corrected time are printed ”3.8”, with a point between the figures, and are given as printed. In the rows for $5^h\ 26^m$ and $5^h\ 40^m\ 45^s$ the word *dub.* (”doubtful”) stands alone in the distance column, with no distance. The Notes column is not ruled into rows: its one paragraph is placed in the row beside which it begins. After ”dirigebat.” in the note a small mark stands that is not read [?]; the sense does not depend on it.]

Observation VI of the Comet, made on the morning of 1652 December 28, new style [Cometæ Obſervatio VI. Anno 1652, die 28 Decemb. St. n. mane habita.]

Mechanical clock [Horologium artificiale.] (h m s)	Altitudes of the fixed stars and of the comet (° ′ ″)	Azimuths of the fixed stars and of the comet (° ′)	Time corrected from the altitudes (h m s)	Distances of the fixed stars and of the comet	Notes [Animadvertenda.]
$12^h\ 1^m\ 15^s$	*Comet* 50° 34′ 10″	81° 37′ west	$11^h\ 52^m\ 31^s$	doubtful	
$12^h\ 22^m\ 30^s$	47° 31′ 40″	86° 25′ west	$12^h\ 13^m\ 46^s$	doubtful	
$1^h\ 10^m\ 0^s$	*Left shoulder*	*of Orion.*	$1^h\ 1^m\ 15^s$	Distance of the comet from the northern horn of ♉ [Taurus]: 26° 33′ 30″, sextant	Clouds sometimes interrupted the observations, so that only a smaller number of distances were taken.
$1^h\ 34^m\ 0^s$	30° 55′ 0″	51° 10′ west	$1^h\ 25^m\ 5^s$		
$1^h\ 40^m\ 0^s$			$1^h\ 31^m\ 10^s$	Distance of the comet from Palilicium: 25° 23′, radius	
$1^h\ 43^m\ 0^s$			$1^h\ 34^m\ 10^s$	Distance of the comet from Palilicium: 25° 23′ 0″, sextant	In the evening we did see the comet with the naked eye; but because the sky was continuously overcast, nothing at all was observed of it with instruments, except the altitude of Palilicium, 28° 34′ 45″, and its azimuth.
$1^h\ 53^m\ 0^s$	*Right shoulder*	*of Orion.*	$1^h\ 44^m\ 10^s$	Distance of the comet from Capella: 22° 52′ 0″, sextant	
$1^h\ 57^m\ 0^s$	32° 47′ 45″		$1^h\ 48^m\ 9^s$		
$1^h\ 59^m\ 0^s$	32° 35′ 45″		$1^h\ 49^m\ 56^s$		
$2^h\ 2^m\ 0^s$			$1^h\ 53^m\ 9^s$	Distance of the comet from the preceding one of the Pleiades: 13° 25′ 0″, radius	

[Six ruled columns as on the page; the azimuth column's unit line reads "Gr.Min." (degrees, minutes). "West" renders the printed *Oc.* A star's name, set in italic above the figures in its cell, is given at the head of the cell. The first ruled row carries two clock lines, given here as two rows. In the rows for $1^h\ 10^m$ and $1^h\ 53^m$ the words "Hum. ſiniſt." / "Hum. dext." stand in the altitude

cell and "Orionis." in the azimuth cell with no figures; the shoulder's figures stand in the next ruled row, below a rule. In the first two rows the word *dub.* ("doubtful") stands alone in the distance column, with no distance. The Notes column is not ruled into rows: each of its two paragraphs is placed in the row beside which it begins. The evening note gives no figure for the azimuth it names. The note prints "altitudo" (nominative) after *præter*; it is rendered "the altitude".]

Observation VII of the Comet, made on the morning of 1652 December 29, new style [Cometæ Obſervatio VII. Anno 1652, die 29 Decembr. St. n. mane habitâ.]

[This heading is printed inside the frame of the table above, in a band across the altitude, azimuth, corrected-time and distance columns; the table below continues that frame and its column heads.]

Mechanical clock [Horologium artificiale.] (h m s)	Altitudes of the fixed stars and of the comet (° ′ ″)	Azimuths of the fixed stars and of the comet (° ′)	Time corrected from the altitudes (h m s)	Distances of the fixed stars and of the comet	Notes [Animadvertenda.]
$4^h\ 9^m\ 0^s$	*Comet* 18° 9′ 15″	49° 28′ S.Oc	$3^h\ 50^m\ 52^s$		
$4^h\ 14^m\ 0^s$	17° 22′ 0″	48° 33′ S.Oc	$3^h\ 55^m\ 52^s$		In this observation the comet, because of the thicker air, was very faint; so it was not possible to draw all the observations from the sky with the care that was due. Moreover, because at that time the comet stood in a lower position, and was so dark and pale that the comet itself could barely, if at all, be made out, and the tail not at all.
$4^h\ 21^m\ 40^s$	*Of Capella* 36° 59′ 0″	west	$4^h\ 3^m\ 31^s$		
$4^h\ 24^m\ 0^s$			$4^h\ 5^m\ 50^s$	Distance of the comet from the northern horn of ♉ [Taurus]: 28° 30′, radius	
$4^h\ 29^m\ 0^s$	*Comet*		$4^h\ 10^m\ 50^s$	Distance of the comet from Capella: 22° 46′, sextant	

Mechanical clock [Horologium artificiale.] (h m s)	Altitudes of the fixed stars and of the comet (° ′ ″)	Azimuths of the fixed stars and of the comet (° ′)	Time corrected from the altitudes (h m s)	Distances of the fixed stars and of the comet	Notes [Animadvertenda.]
$4^h\ 46^m\ 30^s$	$14°\ 26′\ 0″$	$44°\ 23′$ S.Oc	$4^h\ 28^m\ 58^s$	But doubtful, because of the faintness of the light.	Except for one, the distances were observed only with the smaller radius; how much weight they should be given, the calculation will show. The wind was then blowing from the south, and the cold was intense. At that time the comet formed, with the two [stars] in the Head of Medusa, a roughly right-angled triangle; and with the bright [star] of Medusa and the larger one in the foot of Perseus, a nearly straight line.
$4^h\ 53^m\ 0^s$	*Of Capella* $32°\ 58′\ 0″$	west	$4^h\ 35^m\ 52^s$		
$4^h\ 58^m\ 15^s$	$32°\ 11′\ 0″$		$4^h\ 40^m\ 4^s$		
$5^h\ 6^m\ 0^s$	*Comet* $12°\ 7′\ 0″$	$39°\ 28′$ S.Oc	$4^h\ 47^m\ 49^s$	Somewhat more certain.	
$5^h\ 13^m\ 15^s$	*Of Capella* $30°\ 37′\ 45″$		$4^h\ 55^m\ 32^s$		
$5^h\ 29^m\ 0^s$			$5^h\ 10^m\ 40^s$	Distance of the comet from the foot of Perseus: $10°\ 23′$, but doubtful	

[Six ruled columns, continuing the table above. "West" renders the printed *Occid.*, which stands in the azimuth cell with no figures. *S.Oc*, printed without a closing point in all four comet azimuths, is given as printed: the page does not expand it, and its direction is not settled here [?]. In the rows for $4^h\ 9^m/4^h\ 14^m$ and $4^h\ 53^m/4^h\ 58^m\ 15^s$ one ruled row carries two clock lines, given here as two rows. In the row for $4^h\ 29^m$ the word *Cometæ* stands in the altitude cell with no figures; the comet's figures stand in the next ruled row, below a rule. The Notes column is not ruled into rows: each of its two paragraphs is placed in the row beside which it begins. The note prints "circitcr" for *circiter* ("roughly").]

Observation VIII of the Comet, made in the evening of 1652 December 29 [Cometæ Obſervatio VIII. Anno 1652, die 29 Decembr. veſp. habit[[á/á]].]

At about 12 at night I did catch sight of the comet with the naked eye, near the bright star in the Head of Medusa; and as far as could be judged, it stood about 25′ from that star toward the south. It was directing its course as if over the star, yet as though it meant to graze it. In colour it was very pale, and its head had diminished noticeably, nor did its tail appear; but I think this happened chiefly because the air was not clear enough and small clouds were drifting across. For that reason, too, it could not be observed with instruments in any way at all.

Observation IX of the Comet, made on Monday, 1652 December 30, new style [Cometæ Obſervatio IX. Anno 1652, die Lunæ, 30 Decembr. St. n. peracta.]

Mechanical clock [Horologium artificiale.] (h m s)	Altitudes of the fixed stars and of the comet (° ′ ″)	Azimuths of the fixed stars and of the comet (° ′)	Time corrected from the altitudes (h m s)	Distances of the fixed stars and of the comet	Notes
$5^h\ 38^m\ 0^s$			$5^h\ 29^m\ 37^s$	Distance of the comet from Palilicium: 31° 45′ 30″, sextant	The head of the comet was much diminished, and its light very weak, so that it could be observed through the sights only with difficulty; nevertheless a tail also appeared, though a shorter one, as can be seen in the drawing of this observation. The comet was directing the tail roughly toward the left knee of Perseus.
$5^h\ 39^m\ 30^s$	*Of Palilicium* 29° 45′ 45″		$5^h\ 31^m\ 7^s$	Distance of the comet from Palilicium: 31° 44′ 30″, sextant	
$6^h\ 19^m\ 0^s$			$6^h\ 10^m\ 30^s$	Distance of the comet from the northern horn of ♉ [Taurus]: 31° 4′ 0″, sextant	
$6^h\ 34^m\ 0^s$			$6^h\ 25^m\ 30^s$		
$6^h\ 50^m\ 30^s$			$6^h\ 41^m\ 50^s$	Distance of the comet from Capella: 23° 27′ 0″, sextant	The altitudes and azimuths of this comet could not be recorded with the instruments, because of its excessive elevation.

Mechanical clock [Horologium artificiale.] (h m s)	Altitudes of the fixed stars and of the comet (° ′ ″)	Azimuths of the fixed stars and of the comet (° ′)	Time corrected from the altitudes (h m s)	Distances of the fixed stars and of the comet	Notes
$6^h\ 55^m\ 0^s$	*Northern horn of* ♉ *[Taurus]* 43° 26′ 30″	east	$6^h\ 46^m\ 6^s$	Distance of the comet from Palilicium: 31° 42′, radius	
$7^h\ 0^m\ 0^s$	*Of Palilicium*		$6^h\ 51^m\ 10^s$		
$7^h\ 3^m\ 15^s$	40° 43′ 30″	54° 10′ M.Or.	$6^h\ 54^m\ 29^s$		
$7^h\ 6^m\ 35^s$	41° 4′ 0″	53° 22′ M.Or.	$6^h\ 57^m\ 24^s$		
$9^h\ 0^m\ 0^s$			$8^h\ 50^m\ 49^s$	Distance of the comet from the preceding one of the Pleiades: 19° 54′, radius	

[Six ruled columns as on the page; the notes column carries no heading here, and "Notes" is supplied from the column's place in the earlier tables. "East" renders the printed *Orient.*, which stands in the azimuth cell with no figures. *M.Or.*, set small after the two azimuths, is given as printed: the page does not expand it [?]. In the row for $7^h\ 0^m$ the word *Palilicii* stands in the altitude cell with no figures; the star's figures stand in the next ruled row, which carries two clock lines, given here as two rows. The Notes column is not ruled into rows: each of its two paragraphs is placed in the row beside which it begins. The drawing named in the first note is not on this page.]

Observation X of the Comet, made on Tuesday, 1652 December 31, new style [Cometæ Obſervatio X. Anno 1652, die Martis, 31 Decembr. St. n. habita.]

[This heading is printed inside the frame of the table above, in a band across the altitude, azimuth, corrected-time and distance columns; below it the unit line alone is printed again, and the table continues the column heads of the table above.]

Mechanical clock (h m s)	Altitudes of the fixed stars and of the comet (° ′ ″)	Azimuths of the fixed stars and of the comet (° ′)	Time corrected from the altitudes (h m s)	Distances of the fixed stars and of the comet	Notes
$3^h\ 35^m\ 0^s$	☉ *Procyon* 31° 11′ 45″	50° 47′ M.Oc.	$3^h\ 25^m\ 35^s$		The sky was indeed completely clear; but because of the comet's lower position it appeared very pale, and this time we did not notice its tail.
$3^h\ 39^m\ 30^s$	☉ *Of Procyon* 30° 38′ 45″	52° 2′ M.Oc	$3^h\ 28^m\ 52^s$

$4^h\ 3^m\ 0^s$			$3^h\ 53^m\ 0^s$	Distance of the comet from the bend at the hips of Cassiopeia: 24° 41′, radius	

$4^h\ 4^m\ 30^s$	*Of Capella* 36° 26′ 0″		$3^h\ 54^m\ 36^s$		

[Six ruled columns as on the page, headed in full here; "Notes" renders the printed *Animadvertenda*. "West" renders the printed *Occid.*, which stands in the azimuth cell with no figures. *S Oc* (without a point), *S.Oc* and *S.Oc.* are given as printed; the page does not expand them. In the row for $3^h\ 29^m$ the star's name, *Hum. dext. Orionis* ("right shoulder of Orion"), runs across the altitude and azimuth cells; in the next row *Eadem alt.* ("the same, altitude") stands over the altitude. The distance cell of the last row is not closed by a rule and is empty. The Notes column is not ruled into rows: each of its two paragraphs is placed in the row beside which it begins. The drawing named in the second note is not on this page.]

Observation XII of the Comet, made in the evening of Thursday, 1653 January 2, new style [Cometæ Obſervatio XII. Anno 1653, die Jovis, 2 Januarii St. n. veſp. habita.]

Mechanical clock (h m s)	Altitudes of the fixed stars and of the comet (° ′ ″)	Azimuths of the fixed stars and of the comet (° ′)	Time corrected from the altitudes (h m s)	Distances of the fixed stars and of the comet	Notes
$5^h\ 45^m\ 15^s$	*Of Palilicium* 33° 4′ 0″	east	$5^h\ 41^m\ 37^s$		Although the sky was at first quite clear, the comet nevertheless could not be observed with the sextant, because of its feeble light, the smallness of its body and the turbulence of the air; the distances were taken with the radius only.
$5^h\ 47^m\ 0^s$	33° 19′ 0″	east	$5^h\ 43^m\ 36^s$		
$5^h\ 56^m\ 0^s$			$5^h\ 53^m\ 30^s$	Distance of the comet from the bright star in the side of Perseus: 6° 27′, radius	
$6^h\ 11^m\ 0^s$			$6^h\ 7^m\ 30^s$	Distance of the comet from the bright star of Medusa: 4° 52′, radius	
$6^h\ 20^m\ 0^s$			$6^h\ 16^m\ 30^s$		This time we did not see the tail. But the diameter of the body was estimated at 7′ or 8′, so that it displayed a notable size; because of its very feeble light, however, it was hardly conspicuous.

Mechanical clock (h m s)	Altitudes of the fixed stars and of the comet (° ′ ″)	Azimuths of the fixed stars and of the comet (° ′)	Time corrected from the altitudes (h m s)	Distances of the fixed stars and of the comet	Notes
$6^h\ 31^m\ 0^s$			$6^h\ 27^m\ 30^s$	Distance of the comet from the left knee of Perseus: 12° 31′, radius	
$6^h\ 58^m\ 0^s$			$6^h\ 54^m\ 30^s$	Distance of the comet from Capella: 24° 22′, radius	
$7^h\ 4^m\ 30^s$	*Northern horn of* ♉ *[Taurus]* 47° 22′ 0″	east	$7^h\ 0^m\ 46^s$		With the bright star of Medusa and the shoulder of Perseus it formed an almost straight line.
$7^h\ 7^m\ 0^s$	47° 46′ 15″	70° 45′ *M.Or.*	$7^h\ 3^m\ 39^s$		

[Six ruled columns as on the page, headed in full here; "Notes" renders the printed *Animadvertenda*. "East" renders the printed *Orient.*, which stands in the azimuth cell with no figures. *M.Or.* is given as printed; the page does not expand it. The first ruled row carries two clock lines and two altitudes under the one name *Palilicii*, given here as two rows. In the last row the altitude stands under no name, in the ruled row below that of the northern horn of Taurus. The Notes column is not ruled into rows: each of its three paragraphs is placed in the row beside which it begins.]

Observation XIII of the Comet, made on Friday, 1653 January 3, new style [Cometæ Obſervatio XIII. Anno 1653, die Veneris, 3 Januarii St. n. peracta.]

[This heading is printed inside the frame of the table above, in a band across the altitude, azimuth, corrected-time and distance columns; below it the unit line alone is printed again, and the table continues the column heads of the table above.]

Mechanical clock (h m s)	Altitudes of the fixed stars and of the comet (° ′ ″)	Azimuths of the fixed stars and of the comet (° ′)	Time corrected from the altitudes (h m s)	Distances of the fixed stars and of the comet	Notes
$6^h\ 16^m\ 0^s$	*Right shoulder* 20° 36′ 15″	*of Orion* 73° 5′ *M.Or.*	$6^h\ 18^m\ 44^s$	Distance of the comet from Capella: 24° 45′, radius	Although the sky was quite cloudless, the comet's excessive altitude nevertheless made it hard work to examine its intervals from the stars. Hence the distances were observed with the radius alone, and indeed with as much care as that instrument allowed.
$6^h\ 39^m\ 0^s$	*The same, altitude* 23° 31′ 50″		$6^h\ 40^m\ 6^s$	Distance of the comet from the bright star in the side of Perseus: 6° 1′, radius	
$6^h\ 47^m\ 0^s$			$6^h\ 47^m\ 30^s$	Distance of the comet from the bright star of Medusa: 6° 45′, radius	
$6^h\ 50^m\ 30^s$	*Northern horn of* ♉ *[Taurus]* 46° 37′ 30″	72° 55′ *Or.*	$6^h\ 50^m\ 58^s$		
$6^h\ 56^m\ 0^s$			$6^h\ 56^m\ 0^s$	Distance of the comet from the northern horn of Taurus: 35° 15′, radius	In turn, we saw the tail clearly; as far as could be judged, it extended toward the bend of the left side of Perseus.
$7^h\ 0^m\ 0^s$			$6^h\ 59^m\ 50^s$	Distance of the comet from Palilicium: 37° 34′ [printed ”37 34”], radius, but doubtful	
$7^h\ 18^m\ 0^s$	*Northern horn of* ♉ *[Taurus]* 50° 17′ 40″	66° 5′ *Or*	$7^h\ 17^m\ 42^s$		The comet formed something like an equilateral triangle with the bright star of Medusa and the bright side of Perseus.
$7^h\ 59^m\ 0^s$	*Of Procyon* 19° 1′ 20″	73° 17′ *Or*	$7^h\ 58^m\ 12^s$		
$11^h\ 4^m\ 15^s$	*Of Palilicium* 46° 2′ 10″	39° 20′ *Oc.*	$11^h\ 3^m\ 17^s$		
$11^h\ 9^m\ 0^s$	*Of Palilicium* 45° 37′ 45″	40° 41′ *Oc.*	$11^h\ 7^m\ 43^s$		

[Six ruled columns, continuing the frame of the table above; the column heads are supplied from it, since only the unit line is printed here. In the first row the star's name, *Humer. dext. Orion.* ("right shoulder of Orion"), runs across the altitude and azimuth cells. *M.Or.*, *Or.*, *Or* and *Oc.* are given as printed; the page does not expand them. In the row for 7^h 0^m the distance is printed without degree or minute marks. The Notes column is not ruled into rows: each of its three paragraphs is placed in the row beside which it begins.]

Observation XIV of the Comet, made on Saturday, 1653 January 4, new style [Cometæ Obſervatio XIV. Anno 1653, die Saturni, 4. Januarii St. n. habita.]

Mechanical clock (h m s)	Altitudes of the fixed stars and of the comet (° ′ ″)	Azimuths of the fixed stars and of the comet (° ′)	Time corrected from the altitudes (h m s)	Distances of the fixed stars and of the comet	Notes
1^h 55^m 0^s	*Of Palilicium*		1^h 51^m 24^s	Distance of the comet from Palilicium: 37° 57′, sextant	
1^h 57^m 0^s	24° 30′ 45″	west	1^h 53^m 24^s		After eleven in the evening clouds came over, and so put an end to the observation on that occasion. At 2^h, however, the sky shone clear again, so that the comet could once more be observed with the sextant, even though its tail did not appear as clearly as on the previous evening.
2^h 7^m 0^s			2^h 3^m 24^s	Distance of the comet from Capella: 25° 18′ 30″, sextant	
2^h 13^m 0^s			2^h 9^m 24^s	The same distance: 25° 18′ 0″, radius	
2^h 14^m 0^s	*Of Palilicium*		2^h 10^m 24^s	Distance of the comet from Palilicium: 38° 0′, radius	
2^h 19^m 0^s	21° 17′ 45″	west	2^h 15^m 24^s		

Mechanical clock (h m s)	Altitudes of the fixed stars and of the comet (° ′ ″)	Azimuths of the fixed stars and of the comet (° ′)	Time corrected from the altitudes (h m s)	Distances of the fixed stars and of the comet	Notes
$2^h\ 30^m\ 30^s$			$2^h\ 26^m\ 54^s$	Distance of the comet from the bend at the hips of Cassiopeia: 20° 48′ 30″, sextant	
$2^h\ 35^m\ 30^s$	*Of Capella* 45° 39′ 30″	west	$2^h\ 32^m\ 6^s$		
$2^h\ 42^m\ 30^s$	*Comet* 26° 42′ 15″	46° 37′ *S.Oc*	$2^h\ 39^m\ 10^s$		
$2^h\ 56^m\ 30^s$	24° 57′ 0″	45° 13′ *S.Oc*	$2^h\ 53^m\ 30^s$		
$3^h\ 2^m\ 30^s$	*Of Capella* 41° 58′ 30″	66° 46′ *S.Oc*	$2^h\ 59^m\ 6^s$		
$3^h\ 7^m\ 0^s$	41° 23′ 40″	west	$2^h\ 4^m\ 11^s$		

[Six ruled columns as on the page, headed in full here; ”Notes” renders the printed *Animadvertenda*. ”West” renders the printed *Occid.*, which stands in the azimuth cell with no figures. *S.Oc* is given as printed; the page does not expand it. In the rows for $1^h\ 55^m$ and $2^h\ 14^m$ the name *Palilicii* stands alone in the altitude cell, and the altitude figures follow in the next ruled row, against their own clock time. The last two ruled rows each carry two clock lines under one star name, given here as two rows. In the last row the corrected time is printed ”2 4 11” against a clock time of $3^h\ 7^m\ 0^s$, after $2^h\ 59^m\ 6^s$ in the row above; it is given as printed. The Notes column is not ruled into rows: its paragraph is placed in the row beside which it begins.]

Observation XV of the Comet, made on Tuesday, 1653 January 7, new style [Cometæ Obſervatio XV. Anno 1653, die Martis, 7 Januarii St. n: peracta.]

[This heading is printed inside the frame of the table above, in a band across the altitude, azimuth, corrected-time and distance columns; below it the unit line alone is printed again, and the table continues the column heads of the table above.]

Mechanical clock (h m s)	Altitudes of the fixed stars and of the comet (° ′ ″)	Azimuths of the fixed stars and of the comet (° ′)	Time corrected from the altitudes (h m s)	Distances of the fixed stars and of the comet	Notes
1h 31m 0s	*Of Palilicium* 27° 21′ 0″	west	1h 20m 38s		On this day clouds ran across very often, so that the comet's tail could not be made out distinctly. The body, too, looked very slender and thinned, and its light very pale, so that I could scarcely detect it through the sights [pinnacidia], and even then with great labour.
1h 33m 0s	27° 1′ 0″	west	1h 22m 46s		
1h 53m 0s			1h 42m 46s	Distance of the comet from Capella: 25° 46′, radius	
2h 26m 15s	*Bright star in the side* 33° 44′ 0″	*of Perseus* west	2h 15m 54s	Distance of the comet from the bend at the hips of Cassiopeia: 18° 38′, radius, doubtful	It should be noted that on the previous evening, with the Moon shining, we could in no way make out the comet with the naked eye. The chief reason was that at that time it clung so closely to the star in the left shoulder of Perseus that the comet could by no means be told apart from it. On the 7th, however, in the morning at about 3h, with the Moon absent, it appeared clearly enough again, though deprived of its tail, not far from that star: removed from it by about 5′, or to the eye by two digits, or by a whole diameter of the comet, as far as could be judged.
2h 36m 30s			2h 26m 9s	Distance of the comet from the bright star in the foot of Perseus: 22° 0′, radius	
2h 40m 45s	*Left shoulder* 27° 15′ 45″	*of Perseus* 44° 37′ S.Oc.			
2h 50m 0s	*Comet* 25° 36′ 0″	42° 8′ S.Oc.	2h 41m 0s	doubtful	

Mechanical clock (h m s)	Altitudes of the fixed stars and of the comet (° ′ ″)	Azimuths of the fixed stars and of the comet (° ′)	Time corrected from the altitudes (h m s)	Distances of the fixed stars and of the comet	Notes
$3^h\ 2^m\ 0^s$	*Of Capella* 41° 1′ 0″	65° 39′ *S.Oc*	$2^h\ 53^m\ 2^s$	Distance of the comet from the Pole Star: 39° 45′, radius, approximately	
$3^h\ 17^m\ 0^s$			$3^h\ 8^m\ 0^s$	Distance of the comet from the bend at the hips of Cassiopeia: 18° 42′, sextant	
$3^h\ 25^m\ 15^s$	*Of Capella* 37° 57′ 0″	west	$3^h\ 16^m\ 23^s$		
$3^h\ 45^m\ 45^s$	35° 22′ 0″	58° 58′	$3^h\ 36^m\ 44^s$		

[Six ruled columns, continuing the frame of the table above; the column heads are supplied from it, since only the unit line is printed here. In the rows for $2^h\ 26^m\ 15^s$ and $2^h\ 40^m\ 45^s$ the star's name, *Lucid.later. Perſei.* (”bright star in the side of Perseus”) and *Humer. ſin. Perſei.* (”left shoulder of Perseus”), runs across the altitude and azimuth cells. In the row for $2^h\ 40^m\ 45^s$ the corrected-time and distance cells are empty. In the row for $2^h\ 50^m$ the distance cell carries only *dub.* (”doubtful”), with no figures. The last ruled row carries two clock lines under one star name, given here as two rows; its second azimuth, 58° 58′, has no direction word. *S.Oc* and *S.Oc.* are given as printed; the page does not expand them. The Notes column is not ruled into rows: each of its two paragraphs is placed in the row beside which it begins.]

Observation XVI of the Comet [Cometæ Obſervatio XVI.]

On the morning of January 8 we could not observe the comet, because the sky was turbid and very dense clouds veiled it continually; it was nevertheless drawn. It stood a little more than one degree, or about 1° 10′, from that star

in the left shoulder of Perseus, as far as could be estimated. It was, moreover, very slender and feeble in light, so that it almost escaped sight: it was scarcely farther from the star just mentioned than those three in the belt of Perseus are from one another.

In the evening, however, with the Moon shining, the comet could not be seen; and then through the whole of the following night nothing at all was observed, because of continuous darkness.

On January 9, in the evening, at about 6, 7, 8 and 9 o'clock, the Moon for its part being very clear, we went to search for the comet carefully and with the greatest diligence, with the naked eye. Nevertheless we did not notice even a trace of it, although I knew perfectly well in what place it lay and where it was to be sought.

[Margin: The comet no longer seen with the naked eye.]

On January 10, however, at 4, 5 and 6 o'clock in the morning, with the Moon now setting and below the horizon, I again took the greatest pains to make out the comet; but it was sought in vain with the naked eye. I therefore turned on it an eye armed with a telescope, and this task at last succeeded, though not without great fatigue of the eye. And so I did indeed still detect it, but so diminished in body and so feeble in light that it was seen only with great trouble. In size, however, it still nearly equalled a star of the first or second rank [honoris]; but its light appeared much feebler, like that of some nebulous little star. Hence it came about that it was observed, and its place determined, only with great difficulty, and much less could it be drawn. I searched for it again a second time; but because of its rather low northern position, the very many exhalations, and also the presence of the Moon, I could in no way find the comet, however much I strained every nerve of my eyes on it. I am therefore seriously persuaded that it was seen for the last time on this day, and that afterwards it was observed by no one any more: just as it did not appear anywhere to me either, on January 11.

[Margin: Disappearance of the comet.]

Most of the observers saw this phenomenon only up to January 2 and 3; scarcely one or two noted anything of it on the sixth; but on January 9 and 10 no one at all, as far as I have learned so far, noticed it.

[Margin: No one except the author observed the comet up to January 11.]

This came about, I think, because most of them went to search for the comet in the evening hours, and indeed while the Moon was waxing and above the horizon; at that time, as can certainly be seen from my observations, it could by no means be detected. But if they had made observations diligently in the morning hours, especially those who excelled others in keenness of sight, I do not doubt that they would, like me, have seen distinctly not only its body but its tail too. Some observers are indeed found who say that it had scarcely a trace of a tail; but they err on this point, although it may well have seemed entirely so to them, or rather they imagined it to have been so. But what the reason for this is, and why not each and every one who devoted effort to this

comet judged its head, and its tail, to be equally large, will become sufficiently clear below, in its proper place, where its size and true appearance, and its tail as well, are treated expressly.

Section III. Inquiry into the True Time of Each Observation [SECTIO III. Inquiſitio veri temporis ad ſingulas Obſervationes.]

Now that we have set out the observations we made of this comet, with the favour of the Divine Power, we shall proceed rightly and in order if we go on to examine each and every one of them with the greatest care, and as accurately as possible. For if we wished to rest content with the bare observations, as usually happens, we would indeed satisfy historians, and those who delight only in a superficial historical account; but in no way would we satisfy philosophers and astronomers. Such observations are, indeed, to be made chiefly for this purpose: that by their aid the true place of the comet, its distance from the earth, its size and other things of this kind, as pleasant as they are necessary to know, may be rightly investigated and brought to the knowledge of all. This, certainly, is not so easily gained from the observations alone, however diligent; rather, it is a task of arduous effort to penetrate all these matters thoroughly, and at the same time to remove root and branch the doubts that can be raised.

[Margin: For what purpose observations of comets are to be made.]

We have therefore resolved to examine this comet carefully and to the best of our powers, and to pass over nothing that will seem to bear on a rigorous examination. We shall also take diligent pains to set the matter clearly before the eyes, so that even those who have scarcely greeted astronomy from the threshold may fully recognize that everything has been duly and accurately investigated and set out. Beginners, moreover, are to have a method to which they may safely hold in the same way in future with phenomena of this kind. Accordingly, in unravelling this comet, so that it may be plain by what route each point was investigated, we shall also add the calculation itself, derived from the true foundations of trigonometry; and we shall likewise give ready rules for how it is to be carried out concisely by logarithms. In this way it will at the same time be easy for anyone — since the matter is of great importance — to put my calculation back on the anvil the more readily, and to examine it rigorously.

[Margin: The author's purpose is set out.]

Before we come to the calculation itself, however, it is useful to state at what elevation of the pole [Elevatio Poli] these observations were made, since this is the basis and foundation on which everything must be built. Our Danzig elevation of the pole, then, was found to be 54° 23′ in 1612 by the distinguished Petro Crûgero [Peter Crüger], Professor of Mathematics at our Gymnasium and formerly my teacher, whose memory is always to be honoured with gratitude. We too have always used it, especially where we were content with whole minutes; but when greater precision was needed, our own elevation of the pole, namely 54° 22′ 52″, which with the greatest diligence, as

[Margin: The elevation of the pole at Danzig.]

will be evident from our *Machina coelestis* [Machinâ noſtrâ cœleſti], soon to be published, we ourselves drew from the sky — that is what we used. The true elevation of the equator therefore comes out at 35° 37′ 8″. At times, though, before I had settled anything certain on this matter for myself, I also applied to the calculation an elevation of the pole of 54° 22′ 50″, that is, 2″ less, and an elevation of the equator of 35° 37′ 10″. These two seconds, however, detract nothing at all from our calculation, much less harm it. Nor would it have mattered much to mention this, had I not done so for the sake of those who may perhaps weigh our calculations rather more precisely, so that this variation of no importance may not stand in their way.

As for the obliquity of the ecliptic [Obliquitatem Eclipticæ], we have used not that of Tycho Brahe, 23° 31′ 30″, as being too large — as we have learned from reliable observations, and as has been sufficiently stated and demonstrated elsewhere — but that of Gothofredi Wendelini [Govaert Wendelen], namely 23° 30′ 16″, as truer and more consistent with the observations. Our own value, found later, together with that of the most learned Father Riccioli [Giovanni Battista Riccioli], also nearly agrees with it, apart from a very few seconds. We thought it worth pointing this out at this place, my reader, so that you would not be unaware of it.

[Margin: Which obliquity of the ecliptic was used in the calculation.]

Moreover, it will also not be out of place to enter in a table the declinations, right ascensions [Aſcenſiones Rectas], longitudes and latitudes of the fixed stars that we observed and that are also to be subjected to the following calculation, computed from Tycho's sources for the completed year 1652, so that the calculations may afterwards be carried out the more successfully. But how they were derived by logarithms I refrain from saying on this occasion, for brevity's sake. In that table you will find a double declination, right ascension, longitude and latitude of Palilicium. The second of these, drawn with the greatest care from my own observations, we have used for investigating finer matters; the first, Tycho's, we have used only for working out the true time (a task to which so slight a difference does no harm at all).

In addition, we thought it right to set out first two other tables, very useful for the following calculation; in them are entered, for all the observations we made, the true longitudes of the Sun together with its corresponding right ascensions. In the first table, one column shows the uncorrected time by the mechanical clock; the second column, the true place of the Sun; and the third, the right ascension of the Sun. In this table, however, the longitudes of the Sun have not been computed for each individual moment of time — nor is that needed in such a task. In the second table, by contrast, both the individual longitudes of the Sun and the right ascensions, for the true time corrected from the altitudes, have been worked out with the greatest industry from the Rudolphine Tables [Tabulis Rudolphinis] themselves, or rather from the reformed Rudolphine Tables, that is, the Danzig Tables; likewise so that the calculation of the comet

may be carried out the more readily. The method of calculation, since it is well enough known to students of astronomy, I pass over here to save time; meanwhile, however, it is not difficult for anyone to whom it matters, provided they do not grudge the time, to examine all of it.

[Margin: The place of the Sun computed from the Danzig Tables.]

A small table containing, according to Tycho, the declinations, right ascensions, longitudes and latitudes of the same fixed stars that we used in observing this comet and in calculating it.

Names of the fixed stars [Nomina Stellarum fixarum.]	Declination (° ′ ″)	Right ascension (° ′ ″)	Longitude (° ′ ″, sign)	Latitude (° ′ ″)
Aldebaran, or Palilicium	15° 47′ 0″ N	64° 2′ 0″	4° 56′ 42″ ♊	5° 29′ 37″ S
Aldebaran, or Palilicium, according to our observations	15° 46′ 12″ N	64° 1′ 45″	4° 57′ 8″ ♊	5° 29′ 57″ S
The upper horn of ♉, or the star shared with the right foot of Auriga	28° 16′ 30″ N	76° 6′ 35″	17° 43′ 42″ ♊	5° 20′ 30″ N
The preceding star of the Pleiades, or the one at the tip toward the east			25° 31′ 12″ ♉	3° 55′ 30″ N
The bright star of Aries	21° 49′ 0″ N	26° 57′ 0″	2° 49′ 57″ ♉	9° 57′ 30″ N
The first star of Aries	17° 35′ 0″ N	23° 39′ 0″	28° 21′ 0″ ♈	7° 9′ 8″ N
The right shoulder of Orion, the ruddy or bright one	7° 18′ 20″ N	84° 8′ 30″	23° 56′ 12″ ♊	16° 5′ 30″ S
The left shoulder, or the preceding one	5° 59′ 40″ N	76° 42′ 0″	16° 7′ 12″ ♊	16° 52′ 30″ S
Regel, or the bright star in the left foot of Orion	8° 37′ 48″ S	74° 32′ 0″	12° 1′ 12″ ♊	31° 10′ 40″ S
In the left heel of Perseus	31° 7′ 38″ N	50° 39′ 37″	26° 17′ 12″ ♉	12° 8′ 0″ N
Above the foot of Orion, in Eridanus	5° 33′ 8″ S, according to our observation		10° 26′ 12″ ♊	27° 54′ 0″ S
In the hilt of Orion's sword			15° 21′ 42″ ♊	25° 36′ 30″ S
The following one of two others, in Eridanus			8° 23′ 12″ ♊	29° 51′ 30″ S
The preceding one in Eridanus			6° 13′ 42″ ♊	27° 51′ 0″ S
The following one of the two above			4° 29′ 42″ ♊	25° 34′ 0″ S
Procyon, in the thigh of Canis Minor	6° 6′ 0″ N	110° 19′ 0″	21° 2′ 30″ ♋	15° 56′ 30″ S
Capella, shining in the left shoulder of Erichthonius	45° 35′ 30″ N	72° 46′ 0″	17° 0′ 12″ ♊	22° 52′ 15″ N
The bright or shining star in the right side of Perseus	48° 37′ 30″ N	43° 30′ 0″	27° 1′ 12″ ♉	30° 5′ 30″ N
The bright star of Medusa, or Algol	39° 35′ 0″ N	41° 23′ 0″	21° 21′ 0″ ♉	22° 22′ 30″ N
The preceding star below Algol			20° 2′ 0″ ♉	20° 33′ 30″ N

Names of the fixed stars [Nomina Stellarum fixarum.]	Declination (° ′ ″)	Right ascension (° ′ ″)	Longitude (° ′ ″, sign)	Latitude (° ′ ″)
In the left knee of Perseus			0° 52′ 0″ ♊	19° 4′ 0″ N
The following star of the left foot of Perseus			28° 20′ 12″ ♉	11° 18′ 0″ N
The bright star of Cassiopeia's Chair			0° 19′ 42″ ♉	51° 15′ 0″ N
In the bend at Cassiopeia's hips	58° 51′ 0″ N	9° 6′ 0″	9° 11′ 42″ ♉	48° 46′ 30″ N
The Pole Star	87° 27′ 33″ N		23° 46′ 42″ ♊	66° 2′ 0″ N

2

True longitudes and right ascensions of the Sun, for working out the true time from the altitudes of the fixed stars.

1652 December, day	By the mechanical clock, uncorrected (h m s)	True place of the Sun (° ′ ″, sign)	Right ascension of the Sun (° ′ ″)
20	$6^h\ 30^m\ 0^s$ evening		
	$9^h\ 52^m\ 0^s$ evening		
23	$5^h\ 37^m\ 50^s$ evening	2° 40′ 0″ ♐	272° 54′ 12″
	$9^h\ 38^m\ 30^s$ evening	2° 51′ 0″ ♐	273° 6′ 30″
	$10^h\ 31^m\ 45^s$ evening	2° 53′ 0″	273° 8′ 41″
	$11^h\ 23^m\ 30^s$ evening	2° 53′ 0″	273° 8′ 41″
	$12^h\ 0^m\ 20^s$ evening	2° 55′ 0″ ♐	273° 10′ 52″
26	$8^h\ 43^m\ 45^s$ evening	5° 51′ 0″	276° 22′ 32″
	$8^h\ 53^m\ 15^s$ evening	5° 51′ 35″	276° 23′ 0″

3

Table showing the true place and right ascension of the Sun, computed from the Rudolphine Tables.

1652 December, day	By the clock, corrected from the altitudes of the stars (h m s)	True place of the Sun (° ′ ″, sign)	Right ascension of the Sun (° ′ ″)
20	$7^h\ 0^m\ 0^s$ evening	29° 39′ 12″ ♐	269° 37′ 18″
23	$7^h\ 22^m\ 7^s$ evening	2° 44′ 3″ ♐	272° 58′ 55″
	$10^h\ 15^m\ 0^s$ evening	2° 51′ 25″	273° 6′ 58″
23	$10^h\ 57^m\ 20^s$ evening	2° 53′ 14″ ♐	273° 8′ 57″
	$11^h\ 28^m\ 0^s$ evening	2° 54′ 31″	27[?]° 10′ 21″

[2] the table prints the direction of each declination and latitude as *B.* or *Bor.* (north) and *A.* or *Auſt.* (south); these are given here as N and S. Empty cells are empty on the page. "The bright star of Aries" and "The first star of Aries" share one ruled row on the page.

[3] the figure lines are ruled into three groups of three, after the third and the sixth line. The day numbers and the sign ♐ stand only where shown.

1652 December, day	By the clock, corrected from the altitudes of the stars (h m s)	True place of the Sun (° ′ ″, sign)	Right ascension of the Sun (° ′ ″)
24	$1^h\ 27^m\ 30^s$ morning	2° 59′ 36″	273° 15′ 54″
24	$1^h\ 44^m\ 15^s$ morning	3° 0′ 20″ ♑	273° 16′ 42″
26	$6^h\ 0^m\ 0^s$ evening	5° 44′ 30″	276° 15′ 17″
	$9^h\ 0^m\ 34^s$ evening	5° 52′ 10″	276° 23′ 48″

4

True longitudes and right ascensions of the Sun, for working out the true time from the altitudes of the fixed stars.

1652 December, day	By the mechanical clock, uncorrected (h m s)	True place of the Sun (° ′ ″, sign)	Right ascension of the Sun (° ′ ″)
26	$9^h\ 5^m\ 0^s$ evening	5° 51′ 35″ ♑	276° 23′ 0″
	$9^h\ 16^m\ 45^s$ evening	5° 52′ 0″	276° 24′ 43″
	$9^h\ 31^m\ 0^s$ evening	5° 53′ 0″	276° 25′ 0″
	$10^h\ 3^m\ 45^s$ evening	5° 54′ 30″ ♑	276° 25′ 0″
	$11^h\ 3^m\ 30^s$ evening	5° 57′ 0″	276° 29′ 0″
	$11^h\ 7^m\ 15^s$ evening	5° 57′ 0″	276° 29′ 0″
	$11^h\ 33^m\ 0^s$ evening	5° 58′ 0″ ♑	276° 30′ 9″
27	$2^h\ 2^m\ 0^s$ morning	6° 4′ 30″	276° 36′ 40″
	$2^h\ 37^m\ 15^s$ morning	6° 4′ 30″	276° 36′ 40″

5

Table showing the true place and right ascension of the Sun, computed from the Rudolphine Tables [recte: ex, "from" — the page prints &, "and", where the same title on the preceding page prints *ex*].

1652 December, day	By the clock, corrected from the altitudes of the stars (h m s)	True place of the Sun (° ′ ″, sign)	Right ascension of the Sun (° ′ ″)
26	$11^h\ 20^m\ 0^s$ evening	5° 58′ 7″ ♑	276° 30′ 18″
	$11^h\ 38^m\ 22^s$ evening	5° 58′ 55″	276° 31′ 9″
	$11^h\ 44^m\ 48^s$ evening	5° 59′ 10″	276° 31′ 26″
	$11^h\ 50^m\ 31^s$ evening	5° 59′ 27″ ♑	276° 31′ 44″
27	$12^h\ 48^m\ 15^s$ morning	6° 1′ 53″	276° 34′ 23″
	$12^h\ 55^m\ 15^s$ morning	6° 2′ 11″	276° 34′ 42″
	$1^h\ 8^m\ 15^s$ morning	6° 2′ 48″ ♑	276° 35′ 22″
	$1^h\ 24^m\ 45^s$ morning	6° 3′ 25″	276° 36′ 1″
	$2^h\ 6^m\ 0^s$ morning	6° 5′ 12″	276° 37′ 43″
	$5^h\ 14^m\ 5^s$ evening	6° 43′ 51″ ♑	277° 19′ 58″
	$5^h\ 19^m\ 1^s$ evening	6° 44′ 4″	277° 20′ 12″
	$5^h\ 23^m\ 58^s$ evening	6° 44′ 15″	277° 20′ 23″
	$5^h\ 33^m\ 39^s$ evening	6° 44′ 41″ ♑	277° 20′ 52″
	$5^h\ 40^m\ 48^s$ evening	6° 45′ 0″	277° 21′ 12″

[5] this table continues the first Sun table of the preceding page, under a shortened title and a repeated header. The figure lines are ruled into groups of three (one group of two, after the line for 31 December $3^h\ 39^m\ 30^s$). The day numbers, the words "In the year 1653" and the sign ♑ stand only where shown.

1652 December, day	By the clock, corrected from the altitudes of the stars (h m s)	True place of the Sun (° ′ ″, sign)	Right ascension of the Sun (° ′ ″)
	$5^h\ 50^m\ 9^s$ evening	6° 45′ 24″	277° 21′ 39″
	$6^h\ 20^m\ 21^s$ evening	6° 46′ 41″ ♑	277° 23′ 2″
	$11^h\ 44^m\ 31^s$ evening	7° 0′ 27″	277° 37′ 59″
	$11^h\ 52^m\ 31^s$ evening	7° 0′ 49″	277° 38′ 23″
28	$12^h\ 13^m\ 46^s$ morning	7° 1′ 43″ ♑	277° 39′ 22″
	$1^h\ 34^m\ 10^s$ morning	7° 5′ 10″	277° 43′ 6″
29	$3^h\ 50^m\ 52^s$ morning	8° 12′ 18″	278° 56′ 10″
	$3^h\ 55^m\ 52^s$ morning	8° 12′ 33″ ♑	278° 56′ 26″
	$4^h\ 28^m\ 50^s$ morning	8° 13′ 55″	278° 57′ 55″
	$4^h\ 47^m\ 49^s$ morning	8° 14′ 44″	278° 58′ 48″
	$4^h\ 55^m\ 32^s$ morning	8° 15′ 3″ ♑	278° 59′ 9″
30	$6^h\ 10^m\ 30^s$ evening	9° 50′ 12″	280° 42′ 23″
31	$3^h\ 37^m\ 26^s$ morning	10° 14′ 9″	281° 8′ 20″
	$3^h\ 44^m\ 24^s$ morning	10° 14′ 27″ ♑	281° 8′ 39″
In the year	$4^h\ 15^m\ 16^s$ morning	10° 15′ 48″	281° 10′ 7″

	$2^h\ 40^m\ 45^s$ morning	17° 22′ 0″	288° 49′ 45″
	$3^h\ 2^m\ 0^s$ morning	17° 23′ 30″	288° 50′ 50″
	$3^h\ 25^m\ 15^s$ morning	17° 24′ 0″ ♑	288° 51′ 54″
	$3^h\ 45^m\ 40^s$ morning	17° 24′ 0″	288° 51′ 54″

7

[Margin: Investigation of the true time from the altitudes and azimuths of the fixed stars.]

Now let us turn to the task itself and, from all the observed altitudes and azimuths of the fixed stars, work out the true time, so that afterwards, from that corrected time, every time estimated by the clocks [automata] can be corrected. To make everything the clearer to everyone, and at the same time to hold a torch up for beginners and show the way that I have followed, and that they in turn must tread in similar cases, in this first example of ours let us set out the calculation itself in its full sequence, preceded by a visual demonstration, and supply rules for how everything is derived by spherical triangles, and indeed, with the help of logarithms, by a short route. Since, however, on 20 December, when the comet first shone on us, nothing at all certain was observed with the large instruments, let us begin from 23 December.

[Margin: Example of the calculation.]

Let it be sought, then: in the year 1652, on the 23rd of the current month of December, in the evening, at $5^h\ 37^m\ 50^s$ by the mechanical clock — the estimated time, that is — what the true time was, from the first observed altitude of the Palilicium, 27° 31′ 0″. This is done from the given true place of the Sun at the same estimated time and its right ascension, together with the declination of the star and the elevation of the pole at Danzig, in the following way.

Diagram. An engraved circle representing the sphere, set to the right of the text. The outer circle is the solstitial colure or meridian, with C at upper left, F at the top, E at upper right, B at right, D at lower right and A at left. A straight line from A to B is labelled *Horizon.*; a line from C to D is labelled *Æquator.* [?] (the first letter of this inscription is engraved as either Æ or A). From E an arc runs down-left through the star G (drawn as an asterisk) to I on the line CD; its upper part, E to G, is labelled *Compl. Declin.* (complement of the declination) and its lower part, G to I, *Declinatio.* (declination). The stretch from C to I along CD is labelled *Diſt. à Mer.* (distance from the meridian). A

[7]the table is headed "In the year 1653, January, day". The figure lines are ruled into groups of three, the last group of two. The day number 7 stands level with the middle line of the second group, as set here; the sign ♑ stands only where shown. The first line marks the morning as *man.*, the rest as *m.*

line from F through G down to H on the horizon is labelled *Altitudo.* (altitude) along G–H. The arc from E down to B is labelled *Elevatio Poli.* (elevation of the pole). Along the horizon near A stands *Azimuth.* A dotted line runs from G up to K on the circle; dotted lines run from F up to L, outside the circle, and from L down to E. In the lower right corner: *Autor Sculps.* ("the author engraved it").

- A (left, on the circle): end of the horizon
- B (right, on the circle): end of the horizon
- C (upper left, on the circle): end of the equator
- D (lower right, on the circle): end of the equator
- E (upper right, on the circle): pole of the equator
- F (top, on the circle): vertical point, pole of the horizon
- G (interior, asterisk): the star
- H (on the horizon): foot of the vertical circle through G
- I (on the equator): foot of the declination circle through G
- K (upper left, on the circle): end of the dotted line from G
- L (outside the circle, top right): apex of the dotted lines from F and E[8]

1. In the accompanying diagram let the circle ACFEBD be the solstitial colure, or meridian; AB the horizon, whose pole, or vertical point, is F; CD the equator, whose pole is E. The quadrant of the circle of declination EI, drawn from E through the star G, shows GI, the declination of the star, and IC, its distance from the meridian; the vertical circle, descending through the star G, shows HG, the altitude of the star, and HA, its azimuth.

[Margin: Method of the calculation.]

The whole calculation depends on solving the oblique-angled triangle GFE, so that from all the given sides the angle at E is found, which is measured by the arc CI, namely the distance of the star from the meridian. Therefore, since all the sides are known — FE, namely the complement of the elevation of the pole at Danzig, 35° 37′; GE, the complement of the declination, namely that of the Palilicium, 74° 13′; and HG, the observed altitude of the said Palilicium, 27° 31′ East — you will carry out the calculation itself by logarithms in this way: of the two sides en- closing the sought angle, let the difference be added to the third side and taken from it. From the sum of the logarithms of the half-sum and the half-remainder, subtract the sum of the logarithms belonging to the two sides named above (those enclosing the sought angle): half the remainder is the logarithm of half the sought angle. But to put it more clearly:

1. Let the logarithm of the elevation of the equator, that is, of the complement of the elevation of the pole, EF, be added to the logarithm of the complement of the declination, GE; or, what comes to the same thing, let the antilogarithm of the elevation of the pole be added to the antilogarithm of the declination, GI.

[8] every letter and inscription listed was read on the plate; none is left unread. K and L are not named in the text on this page.

2. Let the difference between the elevation of the equator and the complement of the declination be added to the complement of the altitude and subtracted from it, and let both the sum and the remainder be halved.
3. Let the logarithms of the halves be added; from this sum let the sum of the antilogarithms of the first step be subtracted. Half the remainder is the logarithm of half the distance from the meridian that is sought.
4. Let the whole distance from the meridian so found be added to the right ascension of the star if the altitude was western, but subtracted from the right ascension of the star if it was eastern. The sum or remainder is then the right ascension of the midheaven, that is, of the culminating point. When the right ascension of the Sun is subtracted from this, as it always is, there remains the elongation of the Sun from the meridian, to be converted into time counted from the past noon. For example:

Line	Arc	Degrees	Logarithm	Note
Elevation of the pole at Danzig	EF	54° 23′	Antilog. 54067	
Declination of the Palilicium	GI	15° 47′	Antilog. 3843	*A.*
First sum			57910	
Elevation of the equator		35° 37′		
Complement of the declination ⋆	GE	74° 13′		
Difference		38° 36′		
Complement of the altitude of the star		62° 29′		
Sum		101° 5′		
Half		50° 32½′	25866	Logarithm
		--		
Difference		23° 53′		
Half		11° 56½′	157545	Logarithm
Second sum			183411	
First sum			57910	
Remainder			125501	
Half is the logarithm of the half-distance		32° 16′ 15″62750		
Therefore the whole distance of the Palilicium from the meridian		64° 32′ 30″		
Right ascension of the Palilicium		64° 2′ 0″		
		360° 0′ 0″		
Add the whole circle to the right ascension of ⋆, as usual		424° 2′ 0″		
From this, with the distance from the meridian subtracted, there remains		359° 29′ 30″		*Asc. R. M. C.* (right ascension of the midheaven)
Right ascension of the Sun, subtracted		272° 54′ 12″		
The remainder is the elongation of the Sun from the meridian		86° 35′ 18″		
The hours from the preceding noon corresponding to it		$5^h\ 46^m\ 21^s$		The time
namely the one sought; it therefore differs from the estimated time by		$7^m\ 31^s$		

9

[Margin: Another way of computing the true time.]

In this way the true time was computed from all the altitudes of the fixed stars. Sometimes, too, for greater certainty, we also sought that true time by an entirely different method, namely from the given azimuth and altitude of the star. So here too it is convenient to set out the method of demonstration and of computation, for the benefit of beginners.

In the preceding diagram on p. 21, let a perpendicular GK be dropped to the meridian. This must first be found in the triangle GFK, namely from the side GF, the complement of the altitude of the star, and the angle GFK, which is measured by the azimuth AH, observed [recte: obſervatum; printed abſervatum] as 78° 26′: the sum of the logarithms of the two givens is the logarithm of the perpendicular KG that is sought. Then, in the other triangle KGE, with the perpendicular KG and GE, the complement of the declination, known, the angle GEK is found, which measures the sought distance of the star from the meridian, CI. That is, the logarithm of GE, the complement of the declination, subtracted from the logarithm of the perpendicular KG just found, leaves the logarithm of the sought angle E, or of the distance of the star from the meridian, CI; by means of this the true time will come out in the usual way.

[Margin: Example of the calculation.]

For example:

Line	De-grees	Loga-rithm	Angle and arcs
Logarithm of the azimuth	78° 26′	2052	
Log. of the complement of the altitude of the Palilicium	62° 29′	12005	
The sum is the log. of the perpendicular KG		14057	
Log. of the complement of the declination of the star, subtracted		3843	
There remains the log. of the distance of the star from the meridian		10214	whose angle is 64° 32′ 35″
Right ascension of the Palilicium, with 360° added			424° 2′ 0″
Remainder, and right ascension of the midheaven			359° 29′ 25″
Right ascension of the Sun from the table, which is always subtracted			272° 54′ 0″
And so the elongation of the Sun from the meridian			86° 35′ 25″

[9]the page sets this calculation as unruled lines, italic labels with roman figures, with short rules under the figures of the second, fifth, seventh, eleventh, thirteenth, eighteenth and twenty-first lines. The columns above follow the page's alignment; the logarithm 62750 stands to the left of 32° 16′ 15″ on the page. The asterisk is the page's own sign; on p. 65 the star G is drawn as an asterisk. The tag *A.* after 3843 is not expanded on the page. The words "The time, namely the one sought" run from the end of the second-last line into the last. The printed difference $7^m\ 31^s$ does not equal the difference between $5^h\ 46^m\ 21^s$ and the estimated clock time of p. 65, $5^h\ 37^m\ 50^s$, which is $8^m\ 31^s$; the figure is given as printed.

10

Converted into time, these give $5^h\ 46^m\ 21\frac{1}{2}^s$, the true time, and indeed, as before, right down to the seconds. This method of finding the true time through the azimuth and the altitude is certainly far quicker than through the altitude alone, provided that the azimuth has been obtained with due care — though recording it correctly takes skill and labour, as those experienced in these matters know best.

[Margin: How the time is to be derived from azimuths.]

Sometimes, too, for greater certainty, we derive the true time from the azimuth alone, by a calculation that is admittedly somewhat longer, but very necessary to know in observations of this kind. It is done in this way. In the obtuse-angled triangle GEF of the figure above, the angle at E is likewise to be found, from the givens FE, the complement of the elevation of the pole, and EG, the complement of the declination of the star, and from the angle F, namely the azimuth. Before we come to that, however, it is necessary first to find, in the smaller triangle FLE drawn with dotted lines, the side LE, from EF, the complement of the elevation of the pole, and the angle EFL, which equals the azimuth, as being its vertical angle AFH. That is: the sum of the logarithms of the two givens is the logarithm of the sought side LE.

2. Let the side FL be found from the two given sides LE and FE. That is: the antilogarithm of the side LE, subtracted from the antilogarithm of the hypotenuse FE, leaves the antilogarithm of the sought side FL.
3. In the same triangle the angle FEL is also to be sought, from the hypotenuse and the side opposite the sought angle. That is: the logarithm of the hypotenuse FE, subtracted from the logarithm of the side FL, leaves the logarithm of the sought angle FEL.[11]
4. And finally, in the larger right-angled triangle GLE, let the angle GEL be found from the givens, namely GE, the complement of the declination of the star, and the side LE, found in the first step. That is: the mesologarithm [Meſologarithmus] of the hypotenuse GE, subtracted (cossically [cosſicè], if need be) from the mesologarithm of the side LE, leaves the antilogarithm of the sought angle GEL. From this angle, once found, let the smaller angle FEL, found in the third step, be taken away, and there will remain the angle GEF, or IEC, the sought distance of the star from the meridian. From it, as before, the elongation of the Sun from the meridian is obtained,

[10] the page sets this calculation as unruled lines, italic labels with roman figures, with short rules under the figures of the second, fourth, sixth and eighth lines. The columns above follow the page's alignment: the words "whose angle" and the figures 64° 32′ 35″ stand on the same line as the logarithm 10214, to its right. Where p. 66 has 64° 32′ 30″, 359° 29′ 30″ and 272° 54′ 12″, this page prints 64° 32′ 35″, 359° 29′ 25″ and 272° 54′ 0″; all are given as printed.

[11] the first step of this second method carries no printed number; the numbering on the page begins at 2.

and consequently the true time itself; we shall illustrate this with the same example of ours.

[Margin: Example of the calculation.]

Step	Line	Degrees	Logarithm	Mark	Result
1.	Complement of the elevation of the pole, FE	35° 37′	Log. 54067		
	Azimuth, CI or FLE	78° 26′	Log. 2052	*A.*	
	The sum is the logarithm of the side EL		56119		34° 47′ 14″ EL
2.	Antilogarithm of the side EL		19689	*S.*	
	Antilog. of the hypotenuse FE		20711		
	The remainder is the side FL, antilog.		1022		8° 10′ 55″ FL
3.	Log. of the hypotenuse FE, the complement of the elevation of the pole		54067	*S.*	
	Logarithm of the side FL		195002		
	leaves the log. of the sought angle FEL		140935		14° 8′ 27″ FEL.
4.	Mesol. of the hypotenuse GE, the complement of the declination of the star		126352	— *S.* cossically, that is, add	
	Mesologarithm of the side LE		36430	+	
	leaves the antilog. of the angle GEL		162782	+	78° 40′ 34″
	from which let the angle FEL be subtracted				14° 8′ 27″
	And you will have the sought angle GEF, or IC, the distance from the meridian				64° 32′ 7″
	The right ascension of the Palilicium, with 360° added, is found to be				424° 2′ 0″
	The remainder is the right ascension of the midheaven				359° 29′ 53″
	Right ascension of the Sun, to be subtracted				272° 54′ 0″
	Therefore the elongation of the Sun from the meridian				86° 35′ 53″

12

Converted into time, this shows $5^{h}\ 46^{m}\ 23\frac{1}{2}^{s}$, the true time sought, exactly as above except for two seconds. You see, therefore, friendly reader, how precisely these methods agree with one another, even though they are entirely different. And although in these observations it has usually not been tedious for me to seek the true time even by all three of these routes together, I do not wish to bring all these calculations before the public; to keep the work from growing

[12] the page sets this calculation as unruled lines, italic labels with roman figures, with short rules under the figures of the second, fifth, eighth, eleventh, fourteenth and seventeenth lines. The columns above follow the page's alignment. The second line names the azimuth "C I vel F L E" as printed. The tags *A.* and *S.* are not expanded on the page; the dash after 126352 and the plus signs after 36430 and 162782 are the page's own marks. The figures of the last six lines are printed without degree, minute and second marks.

to an immense size, it will be enough merely to have shown by what method the true time, which has been entered alongside the preceding observations, was computed. Anyone who wishes, and has the leisure, can recompute one or two examples, if not all of them; I have no doubt whatever that they will find everything was handled by us with the utmost care and good faith.

Section IV. Given the Comet's Altitude, the True Time and the Azimuth, to Find Its Declination and Right Ascension [SECTIO IV. Datis Cometæ altitudine, vero tempore, & Azimutho, inveſtigare ejus Declinationem, & Aſcenſionem Rectam.]

Since the comet was not always observed in the same place in the sky, but now in this region and now in that, the calculation itself must also be demonstrated from different figures, each showing one of the quadrants of the sky. We have therefore thought it worthwhile to set out four such diagrams here, by which every case can be resolved with the greatest ease. Before we present the calculation itself, with its whole analysis, for our first observation, let us first set out the method of that calculation, which is beyond doubt, together with the necessary rules. After that we shall present the remaining examples as briefly as possible, yet in such a way that the principal members of the calculation are still open to everyone, and every suspicion that some error has been committed is forestalled.

I am not afraid of the light, nor of setting everything out clearly, since I am quite certain (vain glory aside) that everything has been worked out with the greatest accuracy — not only as regards the declinations and right ascensions, but all the subsequent results as well. I can affirm this the more safely because, without any outside help whatever, I myself alone set up and checked the calculations of everything presented in this work, not once only but twice.

[Margin: Autor ſolus omnia ſupputavit ac debitè examinavit.] [The author alone computed everything and duly checked it.]

I admit, however, that among the remaining examples some will be found that will seem to some readers partly unsteady. These are certainly to be attributed not to carelessness but solely to the observed azimuths, which run out to about 90°. For I would have you note well that when the azimuth already exceeds 75°, the obtuse angle of the triangle to be solved is too large for the declination and right ascension — and consequently the longitude and latitude as well — to be obtained accurately enough in any way, however diligently the observation was made and however properly the calculation was derived from it. Hence in the business of parallaxes we also attribute less weight to those observations than to the rest. Nevertheless we have gladly set these out worked through as well, so as not to seem to have omitted some on purpose and brought forward only selected ones. But to the matter itself.

[Margin: Quare nonnullæ ſupputationes ex parte vacillare videantur?] [Why do some computations seem partly unsteady?]

In the four figures that follow, the circles and their names correspond entirely to the diagram inserted in Section III, p. 21, so there is no need for me to name them again. Only this needs to be stated: the first figure shows the face of the sky with the comet placed in the eastern, more southerly quadrant; the second in the eastern, more northerly; the third in the western, more southerly; and the fourth in the western, more northerly quadrant. Likewise, in each the perpendicular GK has been drawn from the comet's apparent place to the meridian. For the demonstration of our first example the first of the following figures will serve us, since the azimuth, as is plain, was observed at 48° 19′ towards the east.

[Margin: Analyſis calculi pro declinatione & Aſc. Recta.] [Analysis of the calculation for the declination and right ascension.]

1. In this figure, then, in its triangle GFK, right-angled at K, we are given GF, the complement of the altitude, and the angle GFK, which is measured by the azimuth AH. First let the perpendicular GK be sought, by this rule: the sum of the logarithms of the two givens is the logarithm of the perpendicular sought.

Diagram. The first of four engraved circle diagrams set two by two across the middle of the page. A circle crossed by the horizon from B to A, the equator running from D up towards C, and great circles through F; the comet G is drawn as a star, with a dotted arc from G to K. The numeral 1 is engraved below the centre.

- Capital letters: F (top), E (upper left), K (upper right), C (right), G (at the star), I (below right of G), B (left), H (on the horizon), A (right), D (lower left)
- Compl. Declin. (complement of the declination), on the arc from E to G
- Compl. Alt. (complement of the altitude), on the arc from F to G
- Declin. (declination), on the arc from G to I
- Elevatio Poli. (elevation of the pole), along the circle at upper left
- Diſt. à M. (distance from the meridian), on the arc from I to C
- Horizon., Altitudo. (altitude, on the arc from G to H), Azimuth., Æquator. (equator)
- 1 (the diagram's number)

Diagram. The second diagram, upper right, numbered 2: the same construction mirrored, with A at the left and B at the right.

- Capital letters: F (top), K (upper left), E (upper right), C (left), G (at the star), I (lower left of G), A (left), H (on the horizon), B (right), D (lower right)
- Compl. Decl., on the arc from G towards E
- Comp[?] Alt., on the arc from G to F; the engraved word may or may not carry an l after Comp
- Declin., on the arc from G to I
- Diſt. à M[?], on the arc from C to I; the end of the inscription is not read beyond the M

- Elevatio Poli., along the circle at right
- Azimuth., Altitudo, Horizon., Æquator.
- 2 (the diagram's number)

Diagram. The third diagram, lower left, numbered 3, with B at the left and A at the right.

- Capital letters: F and K (top), E (upper right), D (upper left), G (at the star), I (left, near the horizon), B (left), H (on the horizon), A (right), C (lower right)
- Declinat., on the arc from G towards D
- Diſt. à Mer. (distance from the meridian), on the arc from D to I
- Comp Decl., on the arc from G to E
- Elevatio Poli., along the circle at right
- Horizon., Altitudo, Azimuth, Æquator.
- 3 (the diagram's number)

Diagram. The fourth diagram, lower right, numbered 4, with B at the left and A at the right.

- Capital letters: F (top), E (upper right of F), D (upper left), K (right), G (at the star), A (right), H (on the horizon), I (below the horizon), B (left), C (lower right)
- Compl. Altitud., on the arc from F to G
- Comp. Dec., on the arc from E to G
- Altitud., on the arc from G to H
- Declinatio., on the arc from G to I
- Diſt. à M. S., on the arc from I to C
- Azimuth, Horizon., Æquator.
- 4 (the diagram's number)

Between the two lower diagrams is engraved: *Autor Sculpſit.* [The author engraved it.]

2. In the same triangle, from the two sides GF, the complement of the altitude, and KG, the side just found, let the side KF be sought, as follows: the antilogarithm of the side, subtracted from the antilogarithm of the hypotenuse, leaves the antilogarithm of the side sought.
3. Let this side KF, once found, be added to the side FE, the complement of the elevation of the pole, or the elevation of the equator, 35° 37′ 8″, to give KE — that is, in the first and second quadrants. In the third and fourth, however, they are subtracted from each other, the smaller side from the larger; the reason is evident from the figures.
4. In the right-angled triangle GKE, from the two sides KE and GK, let the hypotenuse GE, that is, the complement of the declination, be sought in this way: the sum of the antilogarithms of the two sides is the antilogarithm of the hypotenuse. Then let this last result, namely the hypotenuse, be subtracted from a quadrant, and the declination itself will remain.
5. In the same triangle GKE, from the two given sides — GE, the hypotenuse, that is, the complement of the altitude of the comet, and GK, found first

— let the angle GEK be found, which measures the distance from the meridian CI, name- ly: the logarithm of the hypotenuse, subtracted from the logarithm of the side, leaves the logarithm of the angle sought.

6. Let the true time be converted into degrees, to give the elongation from the meridian. To this the right ascension of the Sun is always added, and so the right ascension of the midheaven will result. If this is greater than a full circle, its excess — or, if it is less, its complement to 360° — is added to the distance from the meridian in the eastern quadrant; in the western quadrant, however, the latter is subtracted from the former. You will thus have the right ascension of the phenomenon sought; if it is greater than a full circle, let the whole circle be thrown off from it. Note, however, that if the azimuth exceeds a quadrant, so that it grows beyond 90° and inclines towards the north, you must use the supplement to a semicircle of the distance from the meridian, not the simple distance from the meridian. But an example will make the matter clearer.

Let there be sought, then, for the year 1652, December 23, at 7^h 22^m 7^s in the evening — the corrected time — the comet's declination and right ascension, from its observed altitude of 44° 28′ in the east and azimuth of 48° 19′ [Quæratur itaq; ad Annum 1652. d. 23. Decembris, Hor. veſp. 7 22′ 7″ tempus ſcilicet correctum, Cometæ Declinatio & Aſcenſio Recta, ex altitudine ejus 44° 28′ Orient. & Azimutho 48° 19′ Obſervat.]

subtract the distance from the meridian: right ascension of the comet				46° 23′ 32″	*sought*

25

Observation 15 [Obſervatio 15.]

[24] the statement sets "Com." (of the comet) after the azimuth rather than after "altit." From this observation the comet is observed in the east, in the evening, and the calculation closes by taking the complement of the midheaven's right ascension to 360° from the distance from the meridian.

[25] the statement for Observation 14 stands at the foot of the left column, which closes with the column catchword "Log."; the calculation heads the right column. Its last line is worded as in Observations 2–12, though the figure is the distance less the complement.

From the comet's altitude of 51° 16′ in the east and azimuth of 78° 55′, observed in the evening at the true time of December 27, 5^h 23^m 58^s.

Section V. To Find the Comet's Longitudes and Latitudes from Its Distances from Various Fixed Stars, and to Check Them [SECTIO V. Ex diſtantiis Cometæ à diverſis Stellis Fixis, Longitudines, & Latitudines ejus indagare, eaſq; examinare.]

[Margin: Quâ methodo longitudines & latitudines Cometæ ex diſtantiis ſint ſupputatæ.] [By what method the comet's longitudes and latitudes are computed from its distances.]

In the preceding Section the comet's declinations and right ascensions were computed from its given altitudes and azimuths. In a similar way, in this chapter we shall try to find the comet's longitudes and latitudes, that is, its true place with respect to the ecliptic, as accurately as can ever be done, from the very sources of trigonometry, using the comet's distances from various fixed stars, taken by us both with the sextant and with the radius. Since, however, this business is of far greater moment and calls for deeper inquiry, and the calculation is moreover much more laborious and intricate, because of the various cases and the very diverse triangles to be solved, I consider it supremely necessary that each example be demonstrated and computed from its own particular diagram. Next, I consider it necessary also that whatever longitudes and latitudes of the comet are found be checked by other, different distances of stars from the comet, provided sufficient observations are not lacking, so that we may see whether some error has crept in on us, in the calculation or even in the observation itself. This can very aptly be done by this method.

[Margin: Quâ ratione quodlibet exēplum ſit examinatum.] [How each example is checked.]

For once the comet's longitude and latitude have been found, for example from the comet's distances from the right shoulder of Orion and the upper horn of Taurus, let the distance between the comet and Aldebaran [Aldeboræ] likewise be sought by calculation, given, namely, the comet's longitude and latitude and also the longitude and latitude of Aldebaran (though the distance between the comet and Palilicium must no less have been observed at that same time). Does this computed distance also agree entirely with the other, observed one, or not? If these distances agree, apart from a very few minutes, that is an infallible proof both that the observations themselves were duly made and that the comet's place was rightly established. But if the difference between the said distances is of some moment, amounting, that is, to many minutes, it is a sure sign that there has been an error, either in the observation or in the calculation; and for that reason that example must be either corrected or rejected outright.

---

[42] the stated time, $2^h\ 53^m\ 30^s$, gives an elongation of 223° 22′ 30″; the page prints 224° 52′ 30″, which answers to $2^h\ 59^m\ 30^s$. The last two lines are worked from the printed elongation.

[43] the left column closes with the column catchword "Log."; the lower third of the page is blank.

[Margin: Artis fuit Cometā an. 1652 accuratè dimetiri, & quare?] [It took skill to measure the comet of 1652 accurately; and why?]

Indeed, such doubtful observations have sometimes easily crept in, and this is no cause for wonder. Very often not only the vaporous air but also the comet, dim in its light, and its huge head, diffused in rays, prevented it from being observed with complete accuracy at all times and its centre from always being rightly grasped. Hence it truly takes skill, as all practised observers will admit even without my saying so, always to determine comets correctly, unless they are observed with larger instruments, and also by the most practised investigators of the heavens. Yet you will see, my reader, with what diligence our observations (be it said without boasting) were carried out, and how they agree with one another. You will certainly be astonished that, amid such difficulty and subtlety in these matters, everything could be determined so precisely.

[Margin: Tribus obſervationibus opus habemus ad longitudines exquiſitè indagandas.] [We need three observations to find the longitudes exactly.]

When, however, the calculation is to be set up and checked in the way I reported above, three observations of the comet's distances from fixed stars, taken at the same time, must be at hand. From two the longitude and latitude are indeed derived; but in no way is a check made from two observations alone. It is true that in the first example below the longitudes and latitudes were checked from only two distances; but we approached that task by an entirely different method, because at the time of the observation the comet formed a nearly straight line together with two other fixed stars, as we noted near the beginning of Sect. I, the general description.

[Margin: In primâ obſervatione Cometa triangulum æquilaterum conſtituit.] [In the first observation the comet formed an equilateral triangle.]

As for the first observation, from which the comet's longitude and latitude are to be derived, it was made on December 20, at about seven in the evening. At that time, as the figure of the observation itself attests, the comet formed a nearly equilateral triangle with Regel [Rigel], a star of the first magnitude, and the star above the foot of Orion in the river, of the third magnitude. At the same time it also lay roughly on a straight line with two other fixed stars, namely the preceding one in Eridanus and the following one of the two upper ones, according to Tycho. Nearly equilateral, I say, was the triangle the comet formed: for with the radius the distance between the comet and Regel was taken as 3° 7′, and that between the star above Orion's foot and the comet as 3° 25′, while the distance between Regel and the star above Orion's foot is 3° 33′. From these observations, with the help of the figure set beside them, let us now investigate as best we can the comet's true place with respect to the ecliptic.

[Margin: Methodus ſupputandi longitudines & latitudines Cometæ] [Method of computing the comet's longitudes and latitudes]

Diagram. An engraved figure set to the left of the numbered steps. A curved line across the top, labelled "Ecliptica." (the ecliptic), carries the points

G, E, D, O, P from left to right, with the sign of Aries at its right end. Five circles of latitude run down from G, E, D, O and P and converge at A, at the foot of the figure. Three stars and the comet are marked on them: B, labelled "Regel." (Rigel), on the line from G; C, labelled "Sup. ped. Or." (above the foot of Orion), on the line from E; the comet, drawn as a small circle labelled "Cometa" with F just below it, on the line from D; K, labelled "Se[[q/g]]. duar. ſup." (the following [?] of the two upper ones), on the line from O; and L, labelled "Præc. in Er." (the preceding one in Eridanus), on the line from P. Solid lines join B, C and the comet in a triangle, and run from the comet through K to L. Dotted lines run from B to H, from I to the comet, from the comet towards N, and from K towards M. Below A stands the engraver's note "Autor Sculpsit." (the author engraved it).

- G, E, D, O, P (top, along the ecliptic, left to right): points on the ecliptic
- ♈ (top right, end of the ecliptic): the sign of Aries
- Ecliptica. (top, above D): the ecliptic
- A (foot): the south pole of the ecliptic, where the circles of latitude meet
- B (left), Regel.: Rigel
- C (upper left), Sup. ped. Or.: the star above the foot of Orion
- F (centre), Cometa: the comet
- H (left of centre, below the dotted line from B): foot of the perpendicular B H
- I (left of the comet, on the line from E): point on the dotted line to the comet
- K (right of centre): star labelled "Se[[q/g]]. duar. ſup." [?]
- L (upper right): star labelled "Præc. in Er."
- M (right, below K): point on the dotted line from K
- N (lower right): point on the dotted line from the comet
- Autor Sculpsit. (below A): the engraver's note

1. Let A, then, be the south pole of the ecliptic; ♈ D E G the ecliptic itself; A D, A E, A G circles of latitude; and B Rigel, C the star above the foot of Orion, and F the comet, together forming that equilateral triangle. First, in triangle A C B, the perpendicular B H is to be found from the complement of Rigel's latitude, taken as hypotenuse, and from the angle H A B, or E A B, of the opposite side, which is measured by the difference E G of the stars' longitudes, namely ♈ E of the star above Orion's foot and ♈ G of Rigel. This is very easily done, for the sum of the logarithms of the two given quantities is the logarithm of the perpendicular H B sought.
2. In the right triangle A H B, let A H be sought, given the hypotenuse A B, the complement of Rigel's latitude, and the perpendicular H B just found, in this way: the antilogarithm of the side, subtracted from the antilogarithm of the hypotenuse, leaves the antilogarithm of the side

sought, A H. If you subtract this side A B from the complement of the latitude of the fixed star above Orion's foot, you will have H C.[44]

[Margin: Ratio cal- culi.] [The calculation.]

3. In the smaller triangle H C B, the distance between the fixed star above Orion's foot, C, and Rigel, B, must also be sought at the same time, together with the angle H C B. That distance C B, the hypotenuse of the same triangle, is found from the sum of the antilogarithms of the two remaining sides: H C, just found, and the perpendicular H B. The acute angle H C B, in turn, comes out of the logarithm that remains when the logarithm of the hypotenuse C B is subtracted from the logarithm of the side H B.
4. In the larger, equilateral triangle F C B, let the angle F C B be derived from the three given sides in the usual way. The difference of the two sides that enclose the angle sought is added to the third side and subtracted from it. From the aggregate of the logarithms of the half-sum and of the half-remainder, subtract the aggregate of the logarithms belonging to the two sides mentioned above (those enclosing the angle sought); half the remainder is the logarithm of half the angle sought. Then subtract the angle H C B, found above, from the whole angle F C B, and the angle F C A will remain.
5. In triangle A F C the perpendicular F I is sought again, given the angle F C A and the hypotenuse F C, as above under number 1. In turn, the side C I is also found from the two sides F C and the perpendicular F I, in the same way as was done under number 2. From this side C I let A C, the complement of the latitude of the star above Orion's foot, then be subtracted, so as to give I A.[45]
6. Finally, in triangle F A I, given the two sides F I and I A that enclose the right angle, let the hypotenuse F A be found, as you see done likewise under number 3. This hypotenuse is at the same time the complement of the comet's latitude sought. Once it is found, seek in the same triangle the acute angle F A I, in exactly the same way as we did under the same number 3, knowing, that is, the side F I, opposite the angle sought, and the hypotenuse A F, the complement of the comet's latitude. In this case (since the comet is more westerly) let this angle F A I, or D A E, be subtracted from the longitude of the fixed star above Orion's foot, ♈ E; the remainder, ♈ D, is the comet's longitude sought. For example:

Observation I. [Obſervatio I.]

[44] the last sentence prints "Quod latus A B", "this side A B"; the side just found is A H, and in the figure H C is the part of A C below C, A C being the complement of that star's latitude.

[45] the page prints the subtraction this way round; in the calculation overleaf C I, 2° 56′ 0″, is taken from A C, 62° 6′ 0″, leaving I A, 59° 10′ 0″.

Given the comet's distances from Rigel, 3° 7′, and from the fixed star above the foot of Orion, 3° 25′ [?], taken on December 20 at about 7 in the evening, let the comet's longitude and latitude be sought.[46]

[Margin: Examen cal- culi.] [Checking the calculation.]

Having thus found the comet's longitude and latitude, let us test whether its place has been rightly determined. We do so from the fact that at that time, while the comet formed an equilateral triangle, it also lay on a nearly straight line with two other stars: L, the preceding one in Eridanus, of the fifth magnitude, and K, the following one of the two upper ones, of the fourth magnitude. This will become plain if, in the same figure on the preceding page, the angle M L K is found first, in the right triangle K L M, and then also the angle N L F in the triangle F L N, which is likewise right-angled. If these angles are found to be entirely equal, we judge quite rightly that the comet stood on a straight line with those fixed stars, and consequently also that its place has been duly determined. But if the angles are found to be unequal, and the second is the smaller, you may know that the comet deviated from the straight line towards the south; if, however, it is the larger, towards the north; and by as many degrees and minutes as the said angles differ from each other. From this we also safely conclude that there has been some error in the longitude and latitude.

[Margin: Genuinum in- dicium Come- tam cum dua- bus fixis in re- ctâ ſtetiſſe li- neâ.] [A genuine sign that the comet stood on a straight line with two fixed stars.]

1. In the obtuse-angled triangle L A K, let the perpendicular K M and the side A M be sought, given namely A K, the complement of the latitude of the following star of the two others in Eridanus, and the angle L A K, or P A O, the difference of the longitudes of the two stars L and K, in exactly the way that was done under numbers 1 and 2. Then let A M be subtracted from the complement of the latitude, A L, so that M L remains. And so, in the triangle M L K, from the two sides enclosing the right angle, let the angle M L K sought be found by this rule: the logarithm of the side adjacent to the angle sought, taken as defective and added (algebraically, if need be) to the mesologarithm [Meſologarithmo] of the remaining side, gives the mesologarithm of the angle sought.

51 the right-hand column of the calculation. "the star" is printed as an asterisk.

2. By exactly the same method, in the triangle L A F, given A F, the complement of the comet's latitude found in the calculation above, and the angle L A F, the difference in longitude between the comet, ♈ D, and the preceding star in Eridanus, ♈ P, let F N be sought, together with N L, and finally also, as before, the angle N L F sought. For example:

53

This discrepancy is certainly of no moment. For if you set up the calculation correctly, and from the angle M L K found first you duly seek the comet's latitude, it will be evident that at that time the comet deviated from the straight line by no more than 5′, or at most 6′. This could hardly be discerned, especially because of the comet's huge head, which was nearly the size of the Moon. Hence it is known that the comet's place on this day was found accurately enough, even though the observation was made only with the radius and that straight line was judged by us with the naked eye.

Observation 2. [Obfervatio 2.]

Given the comet's distances from the right shoulder of Orion, 28° 22′, and from the upper horn of Taurus, 20° 27′, taken on December 23 at about 10^{h} 15^{m} in the evening, let the comet's longitude and latitude be sought.

Diagram. An engraved figure set to the right of the prose, within a faint rectangular frame. A nearly horizontal line, the ecliptic, runs across the upper part from C at the left to the sign of Aries at the right, with I, H, R, N, G marked above it from left to right. Several lines run down from the ecliptic and converge at A at the foot. Stars, drawn as small asterisks, stand at E (top, labelled "Cornu ♉", the horn of Taurus), D (left, labelled "Humer. luc. Or.", the bright shoulder of Orion, set vertically along the line below it), M (labelled "Palilic.", Palilicium) and P (labelled "Regel.", Rigel). The comet is a small circle at F, labelled "Cometa", just below the ecliptic near G. Solid lines join E to D, E through N to F, D to F, F to M and F to P; dotted lines run from D to K, from the line through H to F, from M to O and from P to Q. Below A stands the engraver's note "Autor Sculpsit." (the author engraved it).

- E (top), Cornu ♉: the upper horn of Taurus
- I, H, R, N, G (above the ecliptic, left to right): points on the ecliptic
- C (left end of the ecliptic): end of the ecliptic
- ♈ (right end of the ecliptic): the sign of Aries
- F (right, just below the ecliptic), Cometa: the comet

[53] the right-hand column of the check calculation.

- M (right of centre), Palilic.: Palilicium [Aldebaran]
- O (right, at the end of the dotted line from M): point on a circle of latitude
- D (left), Humer. luc. Or.: the bright shoulder of Orion
- K (left of centre, at the end of the dotted line from D): point on a circle of latitude
- P (lower centre), Regel.: Rigel
- Q (lower right, at the end of the dotted line from P): point on a circle of latitude
- A (foot): the pole of the ecliptic, where the circles of latitude meet
- Autor Sculpsit. (right of A): the engraver's note

In the accompanying diagram, let A be the pole of the ecliptic; ♈ C the ecliptic; the circles rising from the pole to the ecliptic, circles of latitude; D the right shoulder of Orion; E the upper horn of Taurus, which has a northern latitude; and F the comet. First, then, from the complement of the latitude, A D, horn of Taurus, and the angle E A D, which is measured by H I, the difference of the longitudes of the stars (namely the horn of Taurus and Orion's right shoulder), you will compute the perpendicular D H and A K. Then take A K from A E, so as to have K E.[54]

2. In the triangle K E D, from the two known sides K D and K E, let E D be found, the distance between the fixed stars of Orion's right shoulder and the upper horn of Taurus, and likewise

[Margin: Calculi me- thodus.] [Method of the calculation.]

the angle K E D. 3. With all the sides of the larger triangle D E F given, the angle A E F is found as above. Once it is known, and the side E F is given, seek in turn the perpendicular F L and the side E L, so as to arrive at A L. And so, finally, in the right triangle A L F, given namely the two sides F L and L A, you will find the hypotenuse A F, the complement of the comet's latitude, and also the angle F A L, the difference of the longitudes of the comet and the horn of Taurus. If this difference is subtracted from the longitude of the horn of Taurus, you will have the comet's longitude sought itself.

Quantity	Value	Quantity	Value	Quantity	Value
Longitude of Orion's right shoulder	83° 56′ 12″	Latitude of Orion's shoulder, I D	16° 5′ 30″	Latitude of the horn of ♉, H E	5° 20′ 30″ *North*
Longitude of the upper horn of ♉	77° 43′ 42″	Compl. of the latitude, A D	73° 54′ 30″	Sum, 90° added	95° 20′ 30″ A E
Difference, angle H A I	6° 12′ 30″				

55

[54] the page prints "A D Cornu ♉"; in the figure D is the shoulder of Orion and E the horn of Taurus, and the calculation overleaf takes A D as the complement of the shoulder's latitude. The perpendicular printed here as D H is labelled D K in that calculation, where D K is the dotted line in the figure.

[55] the three groups stand side by side across the page.

[57]

[Margin: Examen calculi.] [Checking the calculation.]

On the same day, the 23rd, in the evening, at $9^h\ 53^m\ 30^s$, the distance between the comet and Palilicium was also taken with the sextant, as 6° 55′. By this distance we shall now test the comet's place just found: does the same distance also come out, given, that is, the longitude and latitude of the comet and of Aldebaran [Aldeboræ]? First, then, we shall find the perpendicular O M in the triangle F A M, from A M, the complement of Aldebaran's latitude, and the angle O A M, or G N, the difference of the longitudes of the comet and Palilicium; and likewise also A O, so that O F results when the subtraction is made from A F, the complement of the comet's latitude. Then from these two sides found, O M and O F, let the distance F M itself, between the comet and Palilicium, be sought in the triangle M O F, in the way described above.[58]

60

The distance found, however, differs from the observed distance of the comet and Aldebaran by only 2′ 15″, which shows that the comet's place was determined accurately. We shall also try this by the distance of the comet and Regel observed on the same day, at $10^h\ 38^m$ in the evening, if by the same method the perpendicular P Q and the side F Q are found first, and then the distance itself of the comet and Regel is sought from the two sides P Q and F Q just found.

62

By this inquiry the difference between the observed and the computed distance does come out as 11′. But this arises from nothing other than the fact that this observation of the comet and Regel was made about 37^{m} after the distance of the comet and Orion's right shoulder, as the observation journal itself shows. Hence the distance derived from the calculation also necessarily had to be 11′ shorter. For in so long a space of time, namely 37^{m}, the comet, as the table of the comet's proper motion attests, advanced a full 11 minutes further upward. It is therefore certain that the comet's place was correctly observed and computed.

[Margin: Vnde differen- tia undecim minutorum ex- orta ſit?] [Where the difference of eleven minutes arose from.]

Observation 3. [Obſervatio 3.]

From the comet's alignment with two fixed stars in the foot of Perseus on one straight line, and from the distances, taken on December 26 at about 6^{h} in the evening, of the comet from the Heel [Calcaneus], 1° 45′, and of the Heel from the following star of Perseus's foot, let the comet's longitude and latitude be sought.

This observation, since it was noticed by many people at once, in the most diverse regions far apart from one another, certainly deserves that the comet's true place be carefully derived from it as well. We shall, however, reach the goal by a somewhat shorter route than was taken in the examples above, because the distances of the fixed stars and the comet did not at that time form a triangle among themselves but a straight line. Now in the following delineation the

[61] the left-hand column of the second check. The last line, "Antil. A P", stands by itself well to the right and lower down, level with the observed distance in the right-hand column, with no figure beside it.

[62] the right-hand column of the second check; "F A" and "F Q" stand in the logarithm column on the page. The remark on the computed distance is printed "dist." before the figures and "Regel." after them.

circles are named as before; F in turn is the comet, E the left heel, and D the following star of Perseus's left foot.

[Margin: Cometam cum duabus fixis in pede Perſei in lineâ rectâ conſtitutum fuiſſe, à plurimis obſervatum eſt.] [That the comet stood on a straight line with two fixed stars in the foot of Perseus was observed by very many.]

Diagram. An engraved figure in a ruled frame, set to the left of the prose. From A at the top three arcs, circles of latitude, descend to the ecliptic at the foot, meeting it at H, N and G from left to right; the sign of Aries stands at the right end of the ecliptic, beyond G. A star at D on the left arc, a star at E on the middle arc and a small circle at F on the right arc are joined by one straight line. L and K stand at the left of the left arc, with dotted lines running from L to F and from K to E. At the foot of the frame stands the engraver's note "Aut. Sculpſit." (the author engraved it).

- A (top): the point where the circles of latitude meet
- L, K (left of the left arc): points on the left arc, at the ends of the dotted lines from F and E
- D (left arc): a star
- E (middle arc), Calcan: the Heel
- Se[[g/q]]. in ped. Per (below D and E, with engraved tails to both): the following star in the foot of Perseus [?]
- F (right arc), Com.: the comet
- H, N, G (on the ecliptic, left to right): points on the ecliptic
- ♈ (right end of the ecliptic): the sign of Aries
- Aut. Sculpſit. (foot of the frame): the engraver's note[63]

1. From the difference of the longitudes of the Heel E and the other fixed star D, and from the complement of the latitude of the Heel, let the perpendicular E K and the side K D be found in the triangle A E D. 2. In the triangle E K D, given the sides E K and K D, let the distance of the fixed stars E and D be sought, and likewise the angle E D K. 3. In the larger triangle F D L, since the angle D is entirely equal to the angle E D K found before, there will be no need this time to seek it by a separate calculation (as we did in the examples above, in which the distances form a triangle). Instead you will at once compute the perpendicular F L and the side A L from that same angle F D L and the side F D, which is the sum of the distances F E, of the comet and the Heel, and E D, of the fixed stars. 4. In the triangle F L A you will find A F, the complement of the latitude, and the angle F A L, namely G H, the difference of the longitudes of the comet and the following star in the foot of Perseus. When this is subtracted from the longitude of the star just named, there remains ♈ G, the comet's longitude sought.

[63] the last letters of "Calcan" and of "Per" are crossed by the right-hand arc; the second letter of the abbreviation below D and E has a looped descender and is not clearly g or q.

66

Although this time, for want of observations, we cannot check this place of the comet, the observations that follow nonetheless show amply that the inquiry into the comet's place was carried out correctly.

Observation 4. [Obfervatio 4.]

Given the comet's distances from Palilicium, 21° 32′, and from the upper horn of Taurus, 24° 11′, taken on December 26 at 9^h 0^m 34^s, let its longitude and latitude be sought.

In the adjoining figure [iconismo], let A be the north pole of the ecliptic and ♈ H the ecliptic; the circles descending from the pole to the ecliptic are circles of latitude; F is the comet, M Palilicium, E the upper horn of Taurus, S Capella, and P the Bright Star of Aries. Therefore, once the difference of the longitudes of Palilicium and the horn of Taurus is known, namely N H, the angle M A E, together with the complement of the latitude of the horn of Taurus, there result in the triangle M A E the perpendicular E L and the side L M. 2. In the triangle E L M, from E L and L M, let the distance of Palilicium and the horn of Taurus, M E, be computed, and at the same time the angle L M E. 3. With all three sides of the triangle M F E given, let the angle E M F be sought; if the angle L M E is subtracted from it, the angle A M F will remain. 4. By the distance of the comet and Aldebaran, F M, and the angle A M F just found, let the perpendicular F K and the side M K be found in turn, so that A K results. 5. And finally, from F K and A K, in the triangle F A K, you will compute A F, the complement of the comet's latitude, and the angle F A K, the difference of the longitudes of the comet and Palilicium, namely G N. If you subtract this difference from the longitude of Palilicium, ♈ N, there remains ♈ G, the true longitude of the comet sought.

[66] the right-hand column of the calculation; "A L" stands in the logarithm column on the page.

Diagram. An engraved figure in a ruled frame, set to the right of the prose. From A at the top, arcs descend to the ecliptic, which runs across the foot; on it stand H and V at the left, G in the centre and R at the right, with the sign of Aries at its right end. The stars are drawn as asterisks: S, labelled "Capella.", at the left; E, labelled "Cornu ♉.", lower left; P, labelled "Lucid. ♈.", at the right; and M, labelled "Palilicium.", below the ecliptic. The comet is a small circle at F, labelled "Cometa", in the centre. Straight lines join F to S, E, P and M, and E to M; dotted lines run from S to T, from K to F, from E to L and from P to Q. At the foot, right, stands the engraver's note "Autor Sculpſit." (the author engraved it).

The check is made from the distance of the comet and the Bright Star of Aries, 21° 29′, observed on the same day at 9^{h} 14^{m} 56^{s}: namely by finding, in the triangle P A Q, from A P, the complement of the latitude of the Bright Star of Aries, and the angle P A Q, the difference of the longitudes of the comet F and the Bright Star of Aries, the perpendicular P Q and F Q; and so, in the triangle F P Q, from Q F and P Q, the distance itself of the comet and the Bright Star of Aries, sought by calculation.

The observed distance was				21° 29′ 0″	
Difference between the two distances				5′ 55″	

74

That the distance found is 5′ 55″ greater than the observed one comes from the fact that the distance of the Bright Star of Aries was not taken at the very moment when Aldebaran or the upper horn of Taurus was observed, but was noted about 30^{m} later. And so, since the comet's proper motion in that time, as its table shows, was 10′, the distance found must necessarily also be 5′ greater than the observed one. But if all three observations of the distances could have been made together, they would surely have agreed to the very minute. On this day, therefore, the comet's place was determined best of all.

But for the sake of greater certainty let us submit the comet's place to yet another check, and compute in the usual way, from its true place, the distance of Capella and the comet, since that distance was likewise observed at about that time, namely at $11^{h}\ 20^{m}\ 25^{s}$. In the earlier figure [Schemate], then, and in the triangle F A S, there are given the complement of the latitude of Capella, A S, with the angle F A S, the difference of the longitudes of the comet and Capella, so that the perpendicular S T and the side F T result; and from these two given sides, in the triangle S T F, F S, the distance of Capella and the comet sought, is derived.

76

The observed distance is indeed 6′ greater than the one found. The reason is that the distance of the horn and the comet was noted about 28^{m} later, and so the distances cannot agree to the very minute.

Observation 5. [Obſervatio 5.]

Given the comet's distances from the upper horn of Taurus, 24° 35′, and from Capella, 23° 22′, taken on December 26 at about 11^{h} 48^{m}, let the comet's longitude and latitude be sought.

First, since in this figure F is the comet, S Capella and E the horn of Taurus, let the perpendicular S T and the side T E be found in the triangle E S A. 2. Also the distance itself of the fixed stars Capella and the horn of Taurus, S E, together with the angle S E T, from the perpendicular S T found before and the side T E. 3. With the three sides thus known, the angle F E S is found in the triangle F S E; if the angle S E T is added to it, the angle F E A results. 4. In the triangle F E A, in turn, let the perpendicular F K and the side A K be computed, so that in the triangle F K A, from F K and A K, there result the

[75] the left-hand column of the check. The first line is printed with "S V", where the text of the preceding page names the side A S.

[76] the right-hand column of the check; "A F" and "T F" stand in the logarithm column on the page. The computed distance is printed with "Capell." before the figures and "F S" after them.

complement of the comet's latitude, A F, and also the angle F A K, or G H, the difference of the longitudes of the comet and the horn of Taurus. When this difference is subtracted from the longitude ♈ H, there will remain ♈ G, the longitude of the comet sought.

Diagram. An engraved figure in a ruled frame, set to the right of the prose. From A at the top four arcs, circles of latitude, descend to the ecliptic, which runs across the foot; they meet it at H, N, I and G from left to right, and the sign of Aries stands at the right end of the ecliptic, beyond G. The stars are drawn as asterisks: S, labelled "Capella.", upper left; E, labelled "Cornu ♉", lower left; and B, labelled "Plaiad. antec.", lower right. The comet is a small circle at F, labelled "Com.", at the right. T, K and E lie on the leftmost arc and S on the second; C stands beside the third arc, near F. Straight lines join S to E and to F, E to F, and F to B; dotted lines run from T to S and from K towards F. At the foot, right, stands the engraver's note "Autor Sculpſit." (the author engraved it).

- A (top): the north pole of the ecliptic
- T (left, on the leftmost arc, at the end of the dotted line from S): the foot of the perpendicular S T
- S, Capella.: Capella
- K (left, on the leftmost arc, at the end of the dotted line to F): the foot of the perpendicular F K
- F, Com.: the comet
- C (beside the third arc, near F): a point, not named in the text of this page
- E, Cornu ♉: the horn of Taurus
- B, Plaiad. antec.: the leading star of the Pleiades
- H, N, I, G (on the ecliptic): points on the ecliptic
- ♈ (right end of the ecliptic): the sign of Aries
- Autor Sculpſit. (foot, right): the engraver's note

Now, examining this place of the comet against the leading star of the Pleiades (whose distance from the comet was found at about that time to be 9° 57′), let the perpendicular F C and the side C B be sought in the triangle B F A of the preceding figure itself. Then, with the two sides F C and C B thus found, the distance sought, B F, of the leading star of the Pleiades and the comet, is known in the triangle F C B.

81

Since, therefore, the difference of the distances is only 1′ 24″, it is plain to anyone that there has been no error at all in this place of the comet.

Observation 6. [Obfervatio 6.]

Given the comet's distances from Palilicium, 22° 5′, and from the upper horn of Taurus, 24° 36′, taken on December 27 at 2^h 6^m in the morning, let the comet's longitude and latitude be sought.

Since on page 43 we likewise investigated the comet's position from the distances of Palilicium and the horn of Taurus from the comet, the distance of Palilicium and the horn of Taurus, together with the angle L M E, is already known to us from that very calculation of the fourth observation. Therefore, with all the sides of the triangle F M E thus known, in the adjoining figure [iconismo] (in which F is the comet, M Palilicium, E the horn of Taurus and S Capella), let E M F now be sought; from it let the angle L M E be subtracted, so that the angle A M F becomes evident. By this angle, once found, and the side F M, namely the distance of the comet and Palilicium, let the search be made; then both F K and A K, in the triangle A F M. From these sides there will finally result A F, the complement of the comet's latitude A F, and likewise the angle F A K, or G N, the difference of the longitudes of the comet and Palilicium. When this is subtracted from the longitude of Palilicium, ♈ N, there remains the longitude of the comet sought, ♈ G.

Diagram. An engraved figure in a ruled frame, set to the right of the prose. From A at the top arcs, circles of latitude, descend to the ecliptic, which runs across the foot; on it stand H and V at the left and G at the right, with the sign of Aries at its right end. The stars are drawn as asterisks: S, labelled "Capella.", at the upper left; E, labelled "Cornu ☋.", at the lower left; and M, labelled "Palilicium.", below the ecliptic. The comet is a small circle at F, labelled

[84]

While we make the check by the distance of the comet and Capella, which was found at almost the same time, namely at $1^h\ 40^m$, to be 23° 23′, there is found in the same figure, first, in the triangle A S T, the perpendicular S T, from the complement of the latitude of Capella, A S, and from the difference of the longitudes of Capella and the comet,

[Margin: Examen calculi.] [The check of the calculation.]

namely the angle F A S; and at the same time, from the perpendicular S T so found and the same angle F A S, the side T F; and so finally, in the triangle F T S, by the perpendicular S T and the side T F, the distance itself of the comet and Capella, F S.

86

And from this small difference, since it is scarcely as great as the hourly motion of 30 minutes [?], as the comet's table shows, it is abundantly clear that everything has been determined most correctly.

Observation 7. [Obſervatio 7.]

Given the comet's distances from Palilicium, 24° 16′ 30″, and also from Capella, 22° 48′, taken on December 27 in the evening at about 5^h 38^m 10^s, let the comet's longitude and latitude be sought.

In the present diagram let F be the comet, M Aldebaran, S Capella, and P the Bright Star of Aries. Here the first thing to be sought is the distance of Capella and Palilicium, together with the angle V M S. Therefore, as was done in the earlier examples, we shall compute the perpendicular S V in the triangle A S M, from the complement of the latitude of Capella, A S, and the angle S A M, namely the difference of longitude N H; and then also A V, so that V M results. 2. In the right-angled triangle M V S, with the two sides V S and V M given, which contain the right angle, the distance itself of the fixed stars, S M, is known, and also the angle V M S, once the hypotenuse S M and the side V S are known. 3. From the three sides of the oblique-angled triangle S M F let the angle F M S be sought; if V M S is taken from it, the remainder will be the angle A M F. Then from this angle and the distance of the comet and Aldebaran, F M, let the perpendicular F K and A K be found in the triangle F M A in the usual way. 4. In the right-angled triangle F A K, with the two sides F K and A K thus just found, let A F, the complement of the comet's latitude, be sought, and the angle F A K, or the difference of the longitudes of the comet and Aldebaran; if you take this from the longitude of Palilicium, ♈ N, you will have the longitude of the comet sought, ♈ G.

[85] the left-hand column of the check.

[86] the right-hand column of the check; "T F" stands in the arc column on the page. The computed distance is printed with "Com." before the figures and "& Capel." after them.

89

We shall test this place of the comet by the distance of the Bright Star of Aries and the comet, which was observed at the same time, in the evening at 5^{h} 46^{m} 27^{s}, as 21° 27′ 30″. In the triangle P A F of this figure, therefore, let the perpendicular P Q, falling outside the triangle, be sought from the complement of the latitude of the Bright Star of Aries, A P, and from the difference of the longitudes of the comet and the Bright Star of Aries, namely the angle P A F; and likewise the side Q F, from the side A P and P Q. And so finally, in the triangle P F Q, with P Q and F Q given, the distance sought of the comet and the Bright Star of Aries, P F, is found.

Diagram. An engraved figure set to the right of the prose, with no frame visible on the scan. From A at the top arcs, circles of latitude, descend to the ecliptic, which runs across the foot; on it stand H, N, G and R from left to right, with the sign of Aries at its right end, beyond R. The stars are drawn

[89] the right-hand column of the calculation; "A K" stands in the arc column on the page. The remark "semi- / angul." is set over two lines, the second opened by a printed square bracket. The remark on A F is printed "Cõpl." before the figures and "lat.Com." after them; "ſive" stands between the logarithm of F A K and its degrees, and "GN" after them.

as asterisks: S, labelled "Capella.", at the upper left; P, labelled "Lucid.♈." (the Bright Star of Aries), at the right, on the arc that meets the ecliptic at R; and M, labelled "Palilicium.", below the ecliptic at the lower left. The comet is a small circle at F, labelled "Cometa.", near the centre. Straight lines join S to F, F to P, S down to M, and F down to M; dotted lines run from S to V, from K to F, and from P leftward to a cursive letter standing below F. At the foot, right, stands the engraver's note "Autor Sculpf." (the author engraved it).

92

Therefore the distance found differs from the observed one by no more than 2′ 19″, a difference that is surely of no importance.

Observation 8. [Obfervatio 8.]

Given the comet's distances from Palilicium, 25° 23′, and from the horn of Taurus, 26° 34′, taken on December 28 in the morning at 1^{h} 34^{m} 10^{s}, let its longitude and latitude be sought.

The distances of these fixed stars, namely Palilicium and the horn of Taurus, and also the angle L M E, are already known from the calculation of the fourth observation on pages 43 and 44; so there is no need to repeat the same calculation here again. Instead, the angle E M F must be investigated at once in the triangle F M E, namely from the three given sides. Once it is found, the angle L M E is to be taken from it, so that you have the angle A M F. Next, from the given distance of the comet and Palilicium, F M, and the angle A M F just obtained, you will compute the perpendicular F K and at the same time the side K M, so that the side A K results, namely by subtracting the side K M from the distance of Palilicium from the pole, A M. Finally, with A K and F K thus found, there results in the right-angled triangle F K A the complement of the latitude, A F, A F; and likewise, in the same triangle, the angle F A K, from the hypotenuse A F and the side F K. To this angle the difference of the longitudes of the comet and Palilicium, G N, is equal; it is to be taken from the longitude of Palilicium, and there will remain the longitude of the comet sought, ♈ G.

Diagram. An engraved figure set to the left of the prose, within a lighter rectangular plate impression. From A at the top arcs, circles of latitude, descend to the ecliptic, which runs across the foot; on it stand H, V, N, I and G from left to right, with the sign of Aries at its right end. The stars are drawn as asterisks: S, labelled "Capella", at the upper left; E, labelled "Cornu ♉." (the horn of Taurus), at the lower left; B, labelled "Pleiad." (the Pleiades), at the lower right, above the ecliptic; and M, labelled "Palilic." (Palilicium), below the ecliptic. The comet is a small circle at F, labelled "Cometa", at the right. Straight lines join S to F, E to F, E to M, F to M and F to B; dotted lines run

[92] the right-hand column of the check; "F Q" stands in the arc column on the page. The line for A F is printed "Compl. latit. Corn." although A F is the complement of the comet's latitude. The computed distance is printed "dist." before the figures and "Com.& *" after them; the star is printed as an asterisk.

from S to T, from K to F, from E to L, and from B to D. At the foot, right, stands the engraver's note "Autor Sculpſit" (the author engraved it).

- A (top): the north pole of the ecliptic
- S, Capella (upper left): Capella
- T (upper right, at the end of the dotted line from S): a point on a circle of latitude
- K (centre, at the end of the dotted line from F): a point on a circle of latitude
- F, Cometa (right): the comet
- E, Cornu ♉. (lower left): the horn of Taurus
- L (at the end of the dotted line from E): a point on a circle of latitude
- B, Pleiad. (lower right): the Pleiades
- D (at the end of the dotted line from B): a point on a circle of latitude
- ♈ (right end of the ecliptic): the sign of Aries
- H, V, N, I, G (on the ecliptic, left to right): points on the ecliptic
- M, Palilic. (below the ecliptic): Palilicium
- Autor Sculpſit (foot, right): the engraver's note

Check of the comet's place by the distance of Capella, S, 22° 52′, observed on the same day at 1^h 44^m 10^s.

From the complement of the latitude of S, and the angle S A F, which the difference of the longitudes of Capella and the comet measures, let the perpendicular S T first be found; and likewise, from A S and S T, the side A T, which in turn is to be taken from the complement of the comet's latitude, and T F will remain. Then, with the two sides T F and the perpendicular S T given, the distance sought of the comet and Capella, F S, results.

96

Since the difference is only one minute, it is evident that the comet's place has been determined to a nicety. This is moreover confirmed more than enough by a check against the distance of the leading star of the Pleiades and the comet, which was found to be 13° 25′ at 1^h 53^m 9^s. For first, in the triangle D A B, the perpendicular B D is found from the complement of the latitude of the star, A B, and the angle D A B, which is equal to G I, the difference of the longitudes of the comet and the star; and likewise the side A D, from which A F, the complement of the comet's latitude, is to be taken, and the remainder will be F D. And so, from that side and the perpendicular B D, the distance itself of the comet and the star, F B, is found.

Observation 9. [Obfervatio 9.]

98 the right-hand column of the check; "F D" stands in the arc column on the page. The observed distance is printed "Com. & *", with the star as an asterisk.

99 the left-hand column of the calculation; "C B" stands in the arc column on the page.

100 the right-hand column of the calculation. The computed and observed distances are printed in degrees and minutes only; "Com. & Stellæ." stands after the first.

Given the comet's distances from the horn of Taurus, 28° 30′, and from Capella, 22° 46′, taken on December 29 at 4^h 5^m 50^s, let its longitude and latitude be sought.

In the adjoining figure, in which S is Capella, F the comet and E the horn of Taurus, let the angle F E S first be investigated (since the distance of Capella and the horn, together with the angle S E T, is already known from the calculation of the fifth observation on page 46); and when the angle S E T is added to it, the angle F E A will result. 2. In the triangle F E A, from the given distance of the comet and the horn, F E, and the angle F E A, let the perpendicular F K be sought, and the side K E from F K and F E. K E, subtracted from the complement of the latitude of the horn of Taurus, leaves the side A K. 3. In the triangle F A K, from F K and A K, let A F, the complement of the comet's latitude, be computed; and likewise, from the hypotenuse A F and the perpendicular F K, the angle F A K, or G H, the difference sought of the longitudes of the comet and the horn. It is to be taken, of course, from the longitude of the horn of Taurus, so that the longitude of the comet sought, ♈ G, results.

Diagram. An engraved figure in a ruled frame, set to the left of the prose. From A at the top arcs, circles of latitude, descend to the ecliptic, which runs across the foot; on it stand H and N at the left and G at the right, with the sign of Aries at its right end. The stars are drawn as asterisks: S, labelled "Capella.", at the upper left, and E, labelled "Cornu ♉" (the horn of Taurus), at the lower left. The comet is a small circle at F, labelled "Comet.", at the right. Straight lines join S to F, E to F, and S to E; dotted lines run from S to T and from K to F. At the foot, right, stands the engraver's note "Autor Sculpſ." (the author engraved it).

Observation 10. [Obſervatio 10.]

From the nearly equilateral triangle which the comet forms with Algol and the star preceding it below Algol, on the same day, the 29th, at about 4 or 5 o'clock, let the comet's longitude and latitude be sought.

[102] the left-hand column of the calculation. In the lines for the sides and halves the logarithms stand in a column to the right of the degrees, each preceded by "Log."; the first aggregate is printed "Agg. … prius.". The sides and halves are given in degrees and minutes only, the two halves with a printed ½.

[103] the right-hand column of the calculation; "A K" stands in the arc column on the page. The remark on A F is printed "Cõpl." before the figures and "lat.Com." after them.

In the adjoining drawing let F be the comet, S the Bright Star of Medusa, or Algol, and E the preceding star below Algol. Therefore, first, in the triangle A S E, let the perpendicular S T and the side T E be found in the usual way. 2. In the triangle

S T E, from the two sides just mentioned, the distance itself between Algol and the star preceding below Algol, E S, becomes known. 3. In the same triangle, from the hypotenuse S E and the perpendicular S T, the angle S E T is to be sought. 4. Once the one side E S has been found, everything in the triangle S E F is known at once, since the triangle is equilateral. From all these same sides, F E S, you will therefore compute the angle F E S; and when the angle T E S is added to it, the angle A E F results. 5. In the triangle F E A, find the perpendicular F K; and likewise, in the triangle F K E, from F E and F K, the side K E. When K E is subtracted from A E, A K remains. 6. Finally, in the right-angled triangle F K A, given F K and A K, the complement of the comet's latitude, A F, results; and also, from F K and A F, the angle F A K, the difference of the longitudes H G. If you add this to the longitude of the star preceding below Algol, you will have the longitude of the comet itself that was sought.

Diagram. An engraved figure in a ruled frame, to the right of the prose: the "adjoining drawing" named on p. 96. From A at the top three arcs, circles of latitude, descend to the ecliptic, which runs across the foot; they meet it at G, N and H, left to right, and the sign of Aries stands at the ecliptic's right end. The stars are drawn as asterisks: S on the middle arc, labelled "Algol", and E on the right arc, with K just above it and the label "Præced. ſub Algol" (the preceding star below Algol) engraved vertically beside it. T stands on the right arc, joined to S by a dotted line. The comet is a small circle at F on the left arc, labelled "Cometa"; a dotted line runs from F to K. Straight lines join S to F, S to E, and F to E. At the foot, right, stands the engraver's note "Autor Sculps." (the author engraved it).

- A (top): the north pole of the ecliptic
- S, Algol (middle arc): Algol
- T (right arc, at the end of the dotted line from S): a point on a circle of latitude
- F, Cometa (left arc): the comet
- K (right arc, just above E, at the end of the dotted line from F): a point on a circle of latitude
- E, Præced. ſub Algol (right arc): the star preceding below Algol
- G, N, H (on the ecliptic, left to right): points on the ecliptic
- ♈ (right end of the ecliptic): the sign of Aries
- Autor Sculps. (foot, right): the engraver's note

106

However roughly this observation was made, and with the naked eye, it nevertheless agrees fairly precisely with the earlier calculation. Even so, the place found earlier is rightly to be preferred to this later one as the more accurate.

Observation 11. [Obſervatio 11.]

Given the comet's distances from Palilicium, 31° 45′, and from the horn of Taurus, 31° 4′, taken on December 30 in the evening at 6^{h} 10^{m} 30^{s}, let the comet's longitude and latitude be sought.

Since this calculation rests on exactly the same figure inserted above for the 8th observation, on page 50, and on entirely the same method and demonstration set out there, there is no need to repeat all of it again. It will be enough to

[106] the right-hand column of the calculation. In the first line "Log." stands between the logarithm and the degrees. The star preceding below Algol is marked by a printed asterisk in the line for A E; "A K" stands in the arc column. The remark on A F is printed "Cõpl." before the figures and "lat.Com." after them. No sign of the zodiac and no "B." are printed with the comet's latitude or longitude.

set out here only the bare calculation, both of the comet's true place and of its check.

112

The reason why this difference of the distances is somewhat greater than the earlier one is that this distance from the leading star of the Pleiades was observed with the radius only, and moreover about 40^{m} later than the other intervals, namely those from Palilicium and the horn. The comet's place on this day, December 30, has therefore been derived very well.

Observation 12. [Obſervatio 12.]

Given the comet's distances from the horn of Taurus, 31° 25′, and from Capella, 23° 24′ 30″, taken on December 31 in the morning at 4^{h} 7^{m} 18^{s}, let its longitude and latitude be sought.

Just as the preceding calculation depends on the figure shown for observation 8 on page 50, so the figure inserted for observation 9 on page 52, together with what was adduced there for the demonstration, also serves this calculation of ours entirely. For this reason, this time too, we have set down here nothing but the bare calculation.

Observation 13. [Obſervatio 13.]

Given the comet's distances from Palilicium, 34° 5′, and from the upper horn of Taurus, 32° 45′, taken on January 1 in the year 1653 at 2^{h} 52^{m} 49^{s}, let the comet's longitude and latitude be sought.

Since the comet's place is once again to be investigated from its distances from Aldebaran and from the horn of Taurus, as was done for observation 6 on

[113] the left-hand column of the calculation. In the lines for the sides and halves the logarithms stand to the right of the degrees, each preceded by "Log."; the first aggregate is printed "Agg. … prius.". The logarithm of the half-angle stands to the right of its degrees, followed by "Semiſs.".

[114] the right-hand column of the calculation; "A E" and "A K" stand in the logarithm column. The remark on A F is printed "Cõpl." before the figures and "lat.Com." after them.

page 47, our calculation here certainly also enjoys the same demonstration and method, but, by reason of the check, a somewhat different figure. We therefore now add the calculation here, and indeed only its latter part. For the other quantities, namely the interval between Aldebaran and the horn, and likewise the angle L M E, are already evident from the calculation of observation 4 on page 43.

Diagram. An engraved figure in a faint ruled frame, to the left of the calculation: the "somewhat different figure" for Observation 13 named on p. 99. From A at the top five arcs, circles of latitude, descend to the ecliptic, which runs across the foot; they meet it at H, V, N, G and B, left to right, and the sign of Aries stands at the ecliptic's right end. The stars are drawn as asterisks: D on the rightmost arc, under a cursive label beginning "In flexur. ad."; S, labelled "Capella."; E, labelled "Cornu ♉" (the horn of Taurus); and M below the ecliptic, labelled "Palilic." (Palilicium). The comet is a small circle at F, labelled "Cometa"; dotted lines run from F to T, to K and to C, and from E to L on the ecliptic. Straight lines join S to F, E to F, E to M, M to F and D to F. At the foot, right, stands the engraver's note "Autor Sculps." (the author engraved it).

- A (top): the north pole of the ecliptic
- D, In flexur. ad. Cox Caſ (upper right): a star, "in the bend at the hip of Cassiopeia" (the abbreviations taken as coxam Cassiopeiæ)
- T (left, at the end of a dotted line from F): a point on a circle of latitude
- K (centre, on a dotted line from F): a point on a circle of latitude
- F, Cometa (centre right): the comet
- C (right, at the end of a dotted line from F): a point on the rightmost circle of latitude
- S, Capella. (left): Capella
- E, Cornu ♉ (lower left): the horn of Taurus
- L (on the ecliptic, at the end of the dotted line from E): a point on the ecliptic
- H, V, N, G, B (on the ecliptic, left to right): points on the ecliptic
- ♈ (right end of the ecliptic): the sign of Aries
- M, Palilic. (below the ecliptic): Palilicium
- Autor Sculps. (foot, right): the engraver's note

Check of the calculation by the distance of the comet and Capella, 23° 24′, observed at about the same time, at 3^{h} 3^{m} 48^{s}.

1. In the adjoining figure, in which S is Capella, let the perpendicular F T be derived from A F, the complement of the comet's latitude, and the angle T A F, that is, the difference of the longitudes of the star and the comet. 2. In the same triangle A F T, from F T and A F, let the third side A T be investigated; when it is subtracted from S A, the complement of Capella's latitude, S T will result. 3. In the triangle F T S, with T S and F T thus known, the distance itself of the comet and Capella results.

[115] the calculation of Observation 13, set in a single column to the right of the figure. In the lines for the sides and halves the logarithms stand to the right of the degrees, each preceded by "Log."; the first aggregate is printed "Agg. … prius.". The logarithm of the half-angle stands to the right of its degrees, followed by "Semiſ.". "A K" stands in the arc column. The remark on A F is printed "Cõpl." before the figures and "lat.C." after them.

117

You see, then, friendly reader, that the comet's place for this day has been determined very precisely. But for the sake of greater certainty it is worth testing it in yet another way, namely by the distance of the comet from the star in the bend at the hips of Cassiopeia (since this interval too was observed at that time, at $3^{h}\ 15^{m}\ 47^{s}$), to see whether these distances also agree accurately. Accordingly, in the preceding figure let D be that star in Cassiopeia, at the hips. Let the computation follow the preceding analysis. First, in the triangle C A F, from A F, the complement of the comet's latitude, and the angle at A, which the difference of the longitudes of the star and the comet measures, let the perpendicular F C be sought. Next, in the same triangle, from the two given sides A F and F C, find the third side A C; subtract from it the complement of the star's latitude, so that you have D C. Finally, in the triangle D C F, both sides about the right angle being thus known, the distance sought between the star and the comet itself becomes known.

[Margin: Examen calculi.] (Check of the calculation.)

[116] the left-hand column of the check.

[117] the right-hand column of the check; "S T" stands in the arc column. The remark on the computed distance is printed "&" before the figures and "Capel." after them. The difference stands in the seconds column.

119

Although the difference of the distances may seem to be about 50″, in itself, if you weigh the matter scrupulously, it is none. For the observed interval between the comet and the bend at the hips was noted some minutes later than those of the other stars, Palilicium and the horn of Taurus. Hence the observed interval also came out smaller by about a minute, as the comet gradually approached the star (as the following table of the comet's proper motion shows). And so this inquiry too confirms that the comet's place for this day has been derived exactly, which is what we wanted to show.

Observation 14. [Obſervatio 14.]

Given the comet's distances from Palilicium, 34° 5′, and from Capella, 23° 54′, taken on January 1 at 3^{h} 3^{m} 48^{s}, let the comet's longitude and latitude be sought.

In the seventh observation, on page 49, the comet's true place was likewise computed from the intervals of Palilicium and Capella, after a preliminary demonstration. Since in this case too the demonstration and the method of

[118] the left-hand column of the check.

[119] the right-hand column of the check; "D C" stands in the arc column. The remark on the computed distance is printed "Stell." before the figures and "& C." after them. The difference stands in the seconds column. A stray label "Antil.AF" is printed to the left of the column, between the two columns, level with "Differentia".

calculation are entirely the same, I refer to what was said there at length. Moreover, since the distance of these stars, and likewise the angle V M S, are already established from that observation, let us begin this calculation by computing the angle F M S in the oblique-angled triangle S M F, from all its sides given; but we shall present another figure for the check to be made by the distance of the horn of Taurus and the comet.

Diagram. An engraved figure in a faint ruled frame, below the left-hand column of the calculation and beside the prose that follows: the "other figure" for the check of Observation 14 promised on p. 101. From A at the top four arcs, circles of latitude, descend to the ecliptic, which runs across the foot: the leftmost through E to H, the second through S to T, the third through K and V to N and on below the ecliptic to M, the rightmost through F to G; the sign of Aries stands at the ecliptic's right end. The stars are drawn as asterisks: S, labelled "Capella"; E, labelled "Corn. ♉" (the horn of Taurus); and M below the ecliptic, with a label read as P[?]lilicium (Palilicium). The comet is a small circle at F, labelled "Com." (the comet). Dotted lines run from L to F, from K to F and from S to V. Straight lines join S to F, E to F, S to M and F to M. At the foot, right, stands the engraver's note "Aut Sculps." (the author engraved it).

- A (top): the north pole of the ecliptic
- L (left, at the end of a dotted line from F): a point on the second circle of latitude
- F, Com. (upper right): the comet
- K (centre, at the end of a dotted line from F): a point on the third circle of latitude
- V (centre, at the end of a dotted line from S): a point on the third circle of latitude
- S, Capella (left): Capella
- E, Corn. ♉ (lower left): the horn of Taurus
- N (on the ecliptic): a point on the ecliptic
- ♈ (right end of the ecliptic): the sign of Aries
- G (on the ecliptic, right): a point on the ecliptic
- H, T (on the ecliptic, left): points on the ecliptic
- M, P[?]lilicium. (below the ecliptic): Palilicium; the second letter of the label not settled
- Aut Sculps. (foot, right): the engraver's note

That the comet's place found in the preceding calculation exceeds by about a minute is, you should know, because the observations of Palilicium and Capella were not taken together at the same moment of time; the later one, namely Capella's, was taken about half an hour later. But if, in turn, the comet's place is

[121] the right-hand column of the calculation; "A K" stands in the arc column. The latitude is followed by "Bor.". The longitude ends with the sign of Taurus.

derived from the horn and Capella, between whose observations not so long an interval of time elapsed, as the following calculation will show, you will see that everything agrees, to the seconds, with the earlier calculation of Observation 13. But before we come to that, let us bring the place just found to the test of the distance of the horn and the comet. So we must first seek the perpendicular F L, then L E, and so finally, in the triangle L F E, from the two given sides F L and L E that form the right angle, the distance F E of the comet and the horn, in the usual way.

123

Observation 15. [Obſervatio 15.]

Given the comet's distances from Capella, 23° 54′, and from the horn of Taurus, 32° 45′ 30″, taken on the same day, January 1, and at the same hour, 3^h 3^m 48^s, let the comet's longitude and latitude be sought.

For greater confidence in the matter, it will be no trouble to investigate the comet's place once more from the earlier distances, but with them exchanged,

[122] the left-hand column of the check.

[123] the right-hand column of the check; "L E" stands in the arc column. The second antilogarithm of the perpendicular carries no mark. The remark on the computed distance F E is printed "& Capell." after the figures, although the line computes the distance of the comet and the horn. The difference stands in the seconds column.

namely from those of Capella and the horn, and also to examine that place afterwards by the interval to the bend at the hips of Cassiopeia. For undertaking this calculation we already have to hand, set out in Observation 5 above, on page 46, both the distance of these stars, Capella and the horn, and the angle S E T. So let us proceed at once to seek the angle F E S in the oblique-angled triangle E S F, all of whose sides are known; and once it is found, let us add to it the angle S E T, to make F E A. Next, in the triangle F E A, from F E, the distance of the horn and the comet, and from the angle F E A, let the perpendicular F K be found; and at the same time, in the triangle F E K, from the two given sides F E and F K, the side K E. Let this be subtracted from the complement of the latitude of the horn, and the side A K will result. Further, in the triangle F A K, let the hypotenuse A F, namely the complement of the comet's latitude, be sought from the remaining sides F K and A K; and likewise the angle in the same triangle F A K, namely the difference of the longitudes of the comet and the horn, again from the two sides A F and F K now known. When this is taken from the longitude of the horn, the comet's longitude sought will remain.

Diagram. An engraved figure in a faint ruled frame, to the right of the narrow measure of the prose. From A at the top four arcs, circles of latitude, descend to the ecliptic, which runs across the foot: the leftmost through K and E to H, the second through S to V, the third through F to G, the rightmost through D and C to B; the sign of Aries stands at the ecliptic's right end. The stars are drawn as asterisks: D, under the cursive label "In flex. ad Cox. Ca[?]." (in the bend at the hips of Cassiopeia; the form of its last two s-sorts not settled); S, labelled "Capella."; and E, labelled "Cornu ♉" (the horn of Taurus). The comet is a small circle at F. Dotted lines run from K to F, from F to C and from T to S. Straight lines join D to F, S to F, E to F and E to S. At the foot, right, stands the engraver's note "Autor [?]culps." (the author engraved it), its second word's initial a tall cursive form not settled between S and ſ.

- A (top): the north pole of the ecliptic
- D, In flex. ad Cox. Ca[?]. (upper right): the star in the bend at the hips of Cassiopeia
- K (left, at the end of a dotted line from F): a point on the leftmost circle of latitude
- C (right, at the end of a dotted line from F): a point on the rightmost circle of latitude
- T (left, at the end of a dotted line from S): a point on the leftmost circle of latitude
- S, Capella. (left): Capella
- F (centre): the comet
- E, Cornu ♉ (lower left): the horn of Taurus
- H, V, G, B (on the ecliptic, left to right): points on the ecliptic
- ♈ (right end of the ecliptic): the sign of Aries
- Autor [?]culps. (foot, right): the engraver's note

This place of the comet agrees so precisely, especially with the one derived on page 56 in Observation 13, that nothing could be better: it differs by no

[124] the left-hand column of the calculation of Observation 15. In the lines for the sides and halves the logarithms stand to the right of the degrees, each preceded by "Log."; the first aggregate is printed "Aggr. … prius.". The logarithm of the half-angle stands to the right of its degrees with no prefix. The mark "A." stands after the seconds of the angle S E T.

[125] the right-hand column of the calculation; "A K" stands in the arc column. The longitude of the horn carries no arc letters. The comet's longitude ends with the sign of Taurus.

more than 5″ in longitude, while in latitude the later one is greater by 18″; but that arises necessarily from the proper motion. So the comet's place for this day has been derived as accurately [recte: accuratè, printed accutatè] as could ever be done. The following check bears this out as well.

Check of the comet's true place by the distance of the bend at the hips of Cassiopeia, 24° 46′, observed on the same day at 3^h 15^m 47^s.

127

This difference of a minute arises only from the interval of about 15 minutes of time that elapsed between this observation and the earlier ones. For, as the following table of the comet's proper motion attests, its hourly motion at that time was 4′ in one hour. So the interval of the star and the comet observed at 3^h 15^m 47^s was necessarily also about a minute smaller than it would have been had it been taken at 3^h 3^m 48^s.

Observation 16. [Obſervatio 16.]

Given the comet's distances from Capella, 24° 22′, and from the left knee of Perseus, 12° 31′, taken on January 2 at about 6^h 27^m 30^s, let the comet's longitude and latitude be sought.

[126] the left-hand column of the check.

[127] the right-hand column of the check; "D C" stands alone to the right of the label column. The complement of the star's latitude carries no arc letters.

In the adjoining figure let F be the comet, S Capella, E the left knee of Perseus, C Algol, and B the left side of Perseus. Therefore, first, from the difference of the longitudes of Capella and the left knee of Perseus, and also from the complement of Capella's latitude, the perpendicular S T is to be found in the triangle A T S; and likewise the side A T, namely from A S and the perpendicular S T just found. Subtract A T from A E, the complement of the latitude of Capella, and the remainder will be T E. Then, the two sides about the right angle at T in the triangle E T S being thus known, the distance of these stars, Capella and the left knee of Perseus, results; and likewise the angle T E S, but from the given hypotenuse E S and the other side S T. Now in the triangle F E S all three sides are known: E S from the preceding resolution, the others from observation; so the angle F E S will also be established. Subtract from it the angle T E S, and you will have the angle F E A; so that from it and from F E, the distance of the comet and the knee of Perseus, you can in turn derive the perpendicular F K in the triangle F E K, and at the same time E K from the remaining two sides. To obtain the side A K, E K must be subtracted from E A, the complement of the latitude of the knee of Perseus. Finally, in the triangle F K A, the two sides forming the right angle being thus known, you will compute the hypotenuse A F, the complement, that is, of the comet's latitude. Then, also in the same triangle, from the hypotenuse A F just found and the side F K, you will compute the angle F A K, which is exactly equal to the difference of longitude G N of the comet and the knee of Perseus. If, finally, this difference is taken from the longitude of the left knee of Perseus, the comet's longitude itself, which was sought, results.

Diagram. An engraved figure in a faint ruled frame, to the right of the calculation, for Observation 16 and its check. From A at the top five arcs, circles of latitude, descend to the ecliptic, which runs across the foot from H to the sign of Aries at its right end: the leftmost, curved, through S to H; the second through K, T and E to N; the third through B to M; the fourth through the star labelled "Algol." to P; the rightmost through F and D to G. The stars are drawn as asterisks: B, under the cursive label "Latus Sin Perſei." (the left side of Perseus); S, labelled "Capella"; E, labelled "Genu Sin. Persei" (the left knee of Perseus); and an unlettered star labelled "Algol.". The comet is a small circle at F, labelled "Cometa." (the comet). Dotted lines run from B to I, from K to F, from S to T and from the star Algol to D. Straight lines join B to F, S to F, S to E, E to F and F to the star Algol. At the foot, right, stands the engraver's note "Autor Sculps." (the author engraved it). No letter C is engraved, although the text and the calculation use C (for Algol in the text).

Making the check by the distance of Algol, we shall find in the adjoining figure, in its triangle D A C, the perpendicular D C: given, namely, the angle D A C, the difference of longitude of the comet and of the side of Perseus, and

[128] one long column down the left half of the page. In the remark of the row for the distance E S the value stands between the two names (”Capel. 15° 33′ & gen. Perſ.”). In the rows for the sides E S and F E and for the two halves, the logarithm stands to the right of the degrees after ”Log.”; in the first ”Difference” row, after ”Agg.” and followed by ”prius.”. In the row for the antilogarithm of A F, ”Cōpl.” stands before the degrees and ”lat. C.” after them. The rows for T E and A K carry arc letters only.

[129] these two groups stand to the right of the first two rows of the calculation, across the head of it.

A C, the complement of the latitude of Algol. Then, in the same triangle, the side A D becomes known from A C and D C; from it the complement of the comet's latitude must be subtracted, so as to have D F. And so, from that side, together with D C, which forms the right angle with it, the distance sought between the comet and the left side of Perseus becomes known.

[Margin: Examen calculi.] (Check of the calculation.)

This difference of two minutes is surely of no weight; Tycho himself, the leader of the astronomers, agrees, in his *Progymnasmata* on the comet, pages 50, 54, 62 and elsewhere. For although it often happened to him there that the discrepancy of the distances grew to 3 and 4 minutes, he nevertheless holds that such a divergence takes nothing at all away from the comet's true place.

[Margin: Vnius aut alterius minuti differentiam Tycho inCometis non attendit.] (Tycho pays no attention to a difference of one minute or another in comets.)

But let us submit the comet's place found above to yet another check, and investigate whether the distance of the comet and the left side of Perseus, deduced by calculation, also corresponds exactly to the same distance observed

[130] the left-hand column of the check by the distance of Algol.
[131] the right-hand column of the check; "F D" stands alone, with no label.

at 5^h 53^m 30^s. Let the perpendicular B I therefore be sought, as before, given namely the angle I A B, to which the difference of longitude of the comet and the star is equal, and the complement of the side of Perseus; and at the same time A I, in the usual way. When A I is subtracted from the complement of the comet's latitude, the side I F remains. Finally, from this side and B I, the distance sought between the comet and the side of Perseus is found.

It must therefore be admitted that the comet's true place has been established in the best way of all.

[Margin: Obſervationes adamuſim reſpondent.] (The observations agree to a hair.)

Observation 17 [Obſervatio 17.]

Given the comet's distances from the left side of Perseus, 6° 1′, and from Algol, 6° 45′, taken on January 3 at 6^h 47^m 30^s in the evening, let the comet's longitude and latitude be sought.

[132] the left-hand column of the check by the distance of the left side of Perseus. The first label reads "Compl.latit.lat.Perſei." as printed.

[133] the right-hand column of the check; "I F" stands alone, with no label, and the antilogarithm of the distance carries no arc letters.

And now too it falls to us to demonstrate this calculation from an entirely different figure, bearing in mind that so far we have not yet had occasion to find the comet's place from the distances of these fixed stars. Let F, then, be the comet, B the left side of Perseus, C Algol or the head of Medusa, S Capella, and L the horn of Taurus. Hence the triangle A E B must be considered first; in it are given A B, the complement of the latitude of Perseus, and the angle A, the difference of the longitudes of Algol and the other star; therefore E B results, and also A E, from the remaining two sides. Once the side A E has been found and subtracted from A C, E C will remain; together with E B, this gives the distance of the fixed stars Algol and the left side of Perseus. In turn, from this distance and the side E B, the angle E C B is found. Second: in the triangle F C B, its three sides being thus known, the angle F C B becomes known; from it the angle E C B just found is to be taken away, so that you have the angle F C A. Further, in the right-angled triangle F C K, let the perpendicular F K be derived, given namely F C and the angle F C A just found; and likewise the side K C, from the remaining sides, of course. Let this, moreover, be subtracted from the complement of the latitude of the head of Medusa, and the side A K remains. Finally, in the triangle F A K, from the two sides about the right angle, let the hypotenuse A F be sought, that is, the complement of the comet's latitude; and at the same time the angle F A K, but from A F and F K. If you take this angle from the longitude of Algol, the comet's longitude itself, which was sought, will result.

Diagram. An engraved figure in a faint ruled frame, to the right of the narrow measure of the prose, for Observation 17. From A at the top arcs, circles of latitude, descend to the ecliptic, which runs across the foot from R to the sign of Aries at its right end: two arcs on the left, close together, the outer passing the sign ♉ near its top and L near its foot to R, the inner passing I and S to H; an arc through B to M; an arc through E and C to P; and the rightmost through F to G. K stands left of F, at the arc through C. The stars are drawn as asterisks: B, under the cursive label "Lat. Persei." (the side of Perseus); S, labelled "Capella."; C, labelled "Algol."; and L, labelled "Cornu ♉." (the horn of Taurus). The comet is a small circle at F, labelled "Cometa." (the comet). Dotted lines run from B to E and from K to F, and two long dotted lines run from the two left-hand arcs, near the sign ♉ and near I, towards B and F; where each of these two ends is not settled. Straight lines join B to F, B to C, F to C, S to F and L to F. At the foot, right, stands the engraver's note "Autor Sculpsit." (the author engraved it).

It will now be worth while to weigh this place carefully as well, first by the distance of the comet and the horn, 35° 15′, observed at 6^{h} 56^{m}. Accordingly, given the complement of the comet's latitude and the angle G A R, namely the difference of the longitudes, the perpendicular F Q is found in the triangle F A Q; and likewise A Q, from the other known sides. Then subtract this side A

[135] these two groups stand to the right of the first two rows of the calculation, across the head of it.

[136] the right-hand column of the calculation, its first row level with the fourth and fifth rows of the left-hand column. In the row for the antilogarithm of the complement of the latitude, the arc letters "A F" stand after the logarithm, before the degrees; the row for the angle F A K ends with the letters "G P".

Q from A L, the complement of the latitude of the horn, and Q L will result. From it, finally, and the perpendicular F Q, the distance itself of the comet and the upper horn of Taurus will become evident.

It is therefore evident that everything has been carried out accurately. But let us test again whether this also becomes known through the distance of Capella. Accordingly, in the same order as was done before, let first the perpendicular F I be investigated from similar data, then I S, and finally the distance F S itself.

140

Since this distance of Capella was observed somewhat earlier than the others, it certainly cannot agree so precisely with the one derived by calculation, although the comet's proper motion at that time does not run to so many minutes. The chief reason for this small difference, however, is that these observations were made only with the radius, not with the sextant; so a slight error of this kind easily arose. Meanwhile, the calculation of the preceding check has established more than sufficiently that the comet's place was correctly determined.

Observation 18 [Obſervatio 18.]

Given the comet's distances from Palilicium, 37° 57′, and from Capella, 25° 18′ 30″, taken on January 4 at 1^{h} 51^{m} 24^{s}, let the comet's longitude and latitude be sought.

We have already several times found the comet's place from observations of these fixed stars; hence their distance, and also the angle V M S, are already known to us. Therefore in the oblique-angled triangle F M S, with all the sides given, the angle S M F becomes known at once; if V M S, found above, is subtracted from it, the angle F M K will remain. Next, in the right-angled triangle F K M, let the perpendicular F K be investigated from the hypotenuse F M and the said angle F M K; and likewise, with the help of this and F M, the side K M. When K M is taken from A M, the distance of Palilicium from the pole, the side A K will remain. From this in turn, and the remaining side adjacent to the right angle, let A F, the complement of the comet's latitude, be computed in the triangle F K A; and also the angle F A K, or the difference of the longitudes of Aldebaran and the comet, but from the given F K and the hypotenuse A F. When this difference has been subtracted from the longitude of Palilicium, you will have the comet's longitude sought.

[139] the left-hand column of the check by the distance of Capella.

[140] the right-hand column of the check; "I S" stands alone, with no label; in the row for the distance F S an italic ampersand stands between the logarithm and the degrees.

Diagram. An engraved figure in a faint ruled frame, to the right of the upper part of the calculation, for Observation 18. From A at the top arcs, circles of latitude, descend to the ecliptic, which runs across the foot from H to the sign of Aries at its right end: an arc through S to H; an arc through K and V to N, running on below the ecliptic to M; an arc through F to G; and the rightmost through B and C to D. The stars are drawn as asterisks: S, labelled "Capella."; B, under the cursive label "In flex. ad Cox. Ca[[ſſ/ſs]]." (the star in the bend at the hips of Cassiopeia); and M, labelled "Palilicium". The comet is a small circle at F, labelled "Cometa." (the comet). A dotted line runs from K through F to C, and another from S to V. Straight lines join S to F, B to F, S to M and M to F. At the foot, right, stands the engraver's note "Autor Sculpsit" (the author engraved it).

But in making the check by the distance of the comet and the star in the bend at the hips of Cassiopeia, observed at $2^{h}\ 26^{m}\ 54^{s}$, we found first, from the difference of the longitudes of the comet and the star, and also from the complement of the comet's latitude A F, the perpendicular C F. Then, the two sides C F and A F being thus known, the third side A C results; from it let the complement of the latitude of the star be taken, and the side B C will come out. Finally, in the triangle B C F, given the sides about the right angle, the hypotenuse B F also becomes known, namely the distance of the comet and the star sought.

143

Since this distance of the hips of Cassiopeia was taken about 36^{m} later, the distance found necessarily exceeds the observed interval by about 2′, provided we set out the calculation properly; if you subtract this excess from the difference, a discrepancy of scarcely any moment will remain. We therefore rightly judge that this place of the comet, too, has been correctly determined.

Observation 19 [Obfervatio 19.]

Given the comet's distances from Capella, 25° 46′, and from the bend at the hips of Cassiopeia, 18° 42′, taken on January 7 at 2^{h} 26^{m} 9^{s}, let the comet's longitude and latitude be sought.

Although on this last day of its appearance the comet was observed only with a great deal of labour, both because of passing clouds and because of the smallness of its body and the weakness of its light, we shall nevertheless make the effort to derive its true place from these observations. In the accompanying drawing, then, let F be the comet, S Capella, M the following star of the left foot of Perseus, and B the star in the bend at the hips of Cassiopeia. First, in the right-angled triangle B A E, there are given A B, the complement of the said star, and the angle A, which the difference of the longitudes of the said star and Capella measures; so let B E be sought, and at the same time also A E. When A S, the complement of Capella's latitude, has been taken from this side, E S remains. Second, in the triangle B E S, the two sides about the right angle being thus known, the hypotenuse B S is also given, namely the distance of the hips of Cassiopeia and Capella; and likewise the angle B S A, from B S and B E. Third, in the oblique-angled triangle B F S, let the angle at S be investigated from the three given sides; added to the angle B S A, it makes up the angle F S A. Fourth, in the triangle F A S, since F S and the angle F S A are now known, the perpendicular F L also results; and also the side L S, from the two remaining sides, which is to be taken from A S, the complement of Capella's latitude, so that A L remains. Fifth and last, once F L and A L are known, A F, the complement of the comet's latitude, results in the right-angled triangle F L

143the right-hand column of the check; "B C" stands alone, with no label.

A, and likewise the angle F A S, which is to be subtracted from the longitude of Capella, so that the comet's longitude itself, which is sought, may be had.

Diagram. An engraved figure in a faint ruled frame, to the right of the check, for Observation 19. From A at the top arcs, circles of latitude, descend to the ecliptic, which runs across the foot from I to the sign of Aries at its right end: two arcs on the left, close together, ending at I and H, the outer passing P, the inner L and the star s; an arc through M to N; an arc through F to G; and the rightmost through B and C to D. A star labelled "Polaris" (the Pole Star), with O beside it, and the letter E stand on the upper part of the left-hand arcs. The stars are drawn as asterisks: Polaris; B, under the cursive label "In flex. ad cox. Caſ." (in the bend at the hips of Cassiopeia); s, labelled "Capella"; and M, labelled "Sin. pes Persei" (the left foot of Perseus). The comet is a small circle at F, labelled "Cometa" (the comet). Dotted lines run from E to B, from P and from L towards F, and from F to C; a short dotted line runs from the arc through M to F. Straight lines join Polaris to F, s to B, s to F, B to F and M to F. At the foot, right, stands the engraver's note "Autor Sculpsit." (the author engraved it).

- A (apex): A
- upper left, at the left-hand arcs: Polaris (the Pole Star), with O beside it
- E (left-hand arc, end of the dotted line to B): E
- above B: In flex. ad cox. Caſ. (in the bend at the hips of Cassiopeia)
- B (asterisk): B

[147] the check stands below the caption, to the left of the figure; "K M" stands alone, with no label.

- P (outer left-hand arc): P
- L (inner left-hand arc): L
- C (rightmost arc, end of the dotted line from F): C
- F (comet, small circle): F; label "Cometa" (the comet)
- s (asterisk, a small lower-case letter): s; label "Capella"
- M (asterisk): M; label "Sin. pes Persei" (the left foot of Perseus)
- on the ecliptic, left to right: I, H, N, G, D, and the sign ♈
- foot, right: Autor Sculpsit. (the author engraved it)

This time too, then, the comet's place has been derived accurately enough. But let us test the truth of the matter in yet another way, namely by the distance of the Pole Star, 39° 45′, taken at 2^h 53^m 29^s. The perpendicular F P must be investigated, then O P; and so the distance itself of the comet and the Pole Star, F O, which was to be investigated, will become evident from the two given sides O P and F P.

Line	Arc	Logarithm	Mark	Value	Re-mark

149

[148] the left-hand column of the check by the distance of the Pole Star; a short broken vertical stroke stands after the seconds of the comet's longitude.

[149] the right-hand column of the check; "O P" stands alone, with no label, and the arc letters "A O" and "O P" stand in the logarithm column.

I am indeed surprised that this distance as found does not depart further from the observed one, since so large a distance was taken only with the smaller radius, and the sky, moreover, was so cloudy that it was scarcely possible to carry out this observation as one wished at that time.

Section VI. To Find the Latitudes and Longitudes from the Comet's Declinations and Right Ascensions [SECTIO VI. Ex Cometæ Declinationibus,& Aſcenſionibus Rectis inveſtigare Latitudines, & Longitudines.]

In the preceding section we investigated with the greatest diligence the comet's true longitudes and latitudes from all those observed distances of the comet and the fixed stars, wherever this could conveniently be done. It follows that we now also go on to investigate the same true position of the comet, with respect to the ecliptic, from all the remaining observations, which depend on the comet's altitudes and azimuths. To carry out this business duly, we are given its declinations and right ascensions, already found in Sect. IV; with their help the longitudes and latitudes are computed by the following method. The reckoning of the calculation, in the attached diagrams, is this. In them let the circle A E ♋ B etc. be the solstitial colure [colurus Solſtitiorum]; A ♈ B the equator, whose pole is E; ♎ ♈ ♋ the ecliptic, whose pole is D; E C G the circle of declination, showing the comet's declination G C; D C F the circle of latitude, showing the latitude F C and the longitude from the beginning of Aries, ♈ F; and C the comet. From C let the arc of a great circle C ♈ be drawn, so that two triangles arise with a common hypotenuse, C ♈ G and C ♈ F, right-angled at F and G.

[Margin: Ratio calculi pro inveniendis latitudinibus & longitudinibus ex declin. & Aſc. R.] (Method of calculation for finding the latitudes and longitudes from the declinations and right ascensions.)

First, then, the triangle C ♈ G is to be solved. In it, given the declination G C and the right ascension ♈ G, namely the two sides enclosing the right angle, let the hypotenuse ♈ C be investigated: the sum, that is, of the antilogarithms of ♈ G and G C is the antilogarithm of the hypotenuse. Then in the same triangle let the angle G ♈ C be sought, from the hypotenuse ♈ C and the declina- tion C G: namely, the logarithm of the hypotenuse subtracted from the logarithm of the declination leaves the logarithm of the angle sought. This angle and the obliquity of the ecliptic are to be subtracted from each other if the declination is northern in a northern sign, or southern in a southern sign; but if it is northern in a southern sign, or southern in a northern sign, they are to be added. The sum or the remainder will be the angle C ♈ F.

Diagram. Three engraved circle diagrams set side by side across the measure, between the first and second paragraphs of the page. In each circle the equator, labelled "Æquator.", runs across from B on the left to A on the right, passing through the sign of Aries near the centre; the ecliptic, labelled "Ecliptica.", runs from the sign of Cancer on the left through the sign of Aries to the sign of Capricorn on the right; the comet C is drawn as an asterisk, and a dotted line

joins C to the sign of Aries. Where the left circle meets the middle one, and the middle meets the right, the letters are printed together as "AB". In the left circle C stands below the equator, and two arcs run from D and E at the foot of the circle through C up to G on the equator and F on the ecliptic. In the middle circle E stands at the top and D at the foot; C stands just above the equator, with F above it on the ecliptic and G below it on the equator. In the right circle E and D stand at the top; C stands high in the circle, above the ecliptic, with F on the ecliptic and G on the equator below it. Below the right circle stands the engraver's note "Autor Sculpsit." (the author engraved it).

- left circle: ♋ (upper left, end of the ecliptic); B (left, end of the equator); F (on the ecliptic); G (on the equator); ♈ (centre); "Æquator." (the equator); C (asterisk, below the equator); "Ecliptica." (the ecliptic); D and E (foot of the circle); ♍ (right, end of the ecliptic)
- between the left and middle circles: AB
- middle circle: E (top); ♋ (left); F; C (asterisk); ♈; "Æquator."; G; "Ecliptica."; ♍ (right); D (foot)
- between the middle and right circles: AB
- right circle: E and D (top); C (asterisk); ♋ (left); F; G; ♈; "Æquator."; A (right, end of the equator); "Ecliptica."; ♍ (right)
- below the right circle: Autor Sculpsit. (the author engraved it)

Now in the triangle C ♈ F, with the hypotenuse and the angle just found known, the latitude C F is found as follows: the sum of the logarithms of C ♈ and of the angle C ♈ F is the logarithm of the latitude. At the same time, in the same triangle, since the two sides, the hypotenuse ♈ C and the latitude C F, are known, the third side ♈ F also results, the longitude of the comet: if, that is, you subtract the antilogarithm of the latitude from the antilogarithm of the hypotenuse ♈ C, you will have the antilogarithm of the longitude ♈ F sought. All the following longitudes and latitudes have been computed by this method. The calculation does not, however, always use the same diagram; sometimes a quite different one is needed, especially when the declination is southern, or northern and at the same time greater than the obliquity of the ecliptic, though the demonstration always remains the same. This will be clear from the calculation of the sixth and the following observations. Let us now set out in order the calculation itself of all those observations from which the longitude and latitude had to be investigated.

Observation 1 [Observatio 1.]

Calculation of the longitude and latitude for the year 1652, December 23, at $7^h\ 22^m\ 7^s$, given the declination 17° 2′ 26″ N. and the right ascension 57° 23′ 30″.

Antil. of the long.	♈ F	52143		53° 34′ 51″	Longitude of the comet

[154] in this calculation the page marks the logarithm of the angle C ♈ F "S." and the antilogarithm of the latitude "A.", the reverse of the other calculations; the figures are added and subtracted as in the others. Both marks are given as printed.

Observation 14 [Obſervatio 14.]

On December 27, at 5^h 23^m 58^s, given the declination 34° 23′ 14″ N. and the right ascension 46° 24′ 41″.

Line	Arc	Logarithm	Mark	Value	Remark
Antil. of the declin.	G C	19207

Section VII. To Compute the Comet's Declinations and Right Ascensions from Its Given Longitude and Latitude [SECTIO VII. Datis Cometæ Longitudine, & Latitudine, ſupputare ejus declinationes, & Aſcenſiones Rectas.]

In Section IV we did indeed investigate the comet's declinations and right ascensions from its altitudes and azimuths; but from the observations that were made by means of distances from fixed stars, the declinations and right ascensions still remain to be computed. Let us therefore now set about finding these too, first giving the demonstration — and indeed from the longitudes and latitudes given, as explored in Sect. V. The demonstration of this calculation is evident from almost the same diagrams that were attached to the calculation of the longitudes in the preceding section; it has seemed good to add them again here as well, for the sake of better understanding.

[Margin: Proceſſus calculi pro eruendis declin. & Aſc.Rectis ex longit. & latit.] (Procedure of the calculation for deriving the declinations and right ascensions from the longitude and latitude.)

1. Thus in the right-angled triangle ♈ F C, given the longitude ♈ F and the latitude F C, the two sides about the right angle, let the hypotenuse ♈ C be sought by this rule, namely: the sum of the given logarithms is the antilogarithm of the hypotenuse ♈ C sought. 2. In the same triangle let there also be computed the angle C ♈ F, from the hypotenuse ♈ C just found and the known latitude of the comet F C, namely: by subtracting the logarithm of the hypotenuse ♈ C from the logarithm of the latitude C F, the remainder will be the logarithm of the angle C ♈ F sought. This angle is to be added to the obliquity of the ecliptic ♋ ♈ B if the latitude is northern in a northern sign, or southern in a southern sign; but it is to be subtracted if the latitude is northern in a southern sign, or southern in

a northern sign, so that the angle C ♈ G results. 3. Now in the triangle C ♈ G, the hypotenuse C ♈ and the angle at ♈ being thus known, the declination C G itself also results: the sum of the given logarithms gives the logarithm of the declination. 4. And lastly, in the same triangle, from that same hypotenuse ♈ C and the declination C G, the third side ♈ G, the right ascension, is also derived: if, namely, the antilogarithm of the declination is subtracted from the antilogarithm of the hyp. ♈ C, you will have the antilogarithm of the right ascension from the nearest equinox. In the first quadrant of the ecliptic this is to be retained as the genuine value; in the second quadrant it is to be subtracted from a semicircle; in the third, added to a semicircle; and in the fourth, subtracted from the whole circle. Thus the right ascension sought, reckoned from the beginning of Aries, will result. For example:

Diagram. Three engraved circle diagrams set side by side across the measure, between the paragraph and the two worked calculations, within a rectangular plate mark. In each circle the equator, labelled "Æquator.", runs across from B on the left to A on the right, passing through the sign of Aries near the centre; the ecliptic, labelled "Ecliptica.", runs from the sign of Cancer on the left through the sign of Aries to the sign of Capricorn on the right; the comet C is drawn as an asterisk, and a dotted line joins C to the sign of Aries. Where the left circle meets the middle one, and the middle meets the right, the letters are printed together as "AB". In the left circle C stands below the equator, and two arcs run from D and E at the foot of the circle through C up to G on the equator and F on the ecliptic. In the middle circle E stands at the top and D at the foot; C stands just above the equator, with F above it on the ecliptic and G below it on the equator. In the right circle E and D stand at the top; C stands high in the circle, above the ecliptic, with F on the ecliptic and G on the equator below it. Below the right circle stands the engraver's note "Autor Sculpsit." (the author engraved it). The text describes these as the diagrams of the preceding section, added again here.

- left circle: ♋ (upper left, end of the ecliptic); B (left, end of the equator); F (on the ecliptic); G (on the equator); ♈ (centre); "Æquator." (the equator); C (asterisk, below the equator); "Ecliptica." (the ecliptic); D and E (foot of the circle); ♑ (right, end of the ecliptic)
- between the left and middle circles: AB
- middle circle: E (top); ♋ (left); F; C (asterisk); ♈; "Æquator."; G; "Ecliptica."; ♑ (right); D (foot)
- between the middle and right circles: AB
- right circle: E and D (top); C (asterisk); ♋ (left); F; G; ♈; "Æquator."; A (right, end of the equator); "Ecliptica."; ♑ (right)

Observation 1 [Obſervatio 1.]

Calculation of the declination and right ascension for the year 1652, December 20, at about 7^h in the evening, given the longitude ♊ 8° 24′ 24″ and the latitude 30° 49′ 1″ S.

Section VIII. To Investigate the Comet's Digressions, or Distances, from the Sun [SECTIO VIII. Cometæ à Sole digreſſiones, ſeu diſtantias inveſtigare.]

Now, in the same way, let us find the comet's elongations from the Sun for all the observations whose longitude and latitude, declination and right ascension have been computed. This is very easily done: it needs the solution of only one right-angled triangle, from the given longitudes of the Sun and the comet and the comet's latitude. For example, in the following diagram let A B D be the ecliptic, E and F its poles, E B and F B circles of latitude, C the comet, C B its latitude, and S the place of the Sun. Therefore, in the triangle right-angled at B, there are known two sides: S B, the difference between the longitudes of the Sun and the comet, and also B C, the comet's latitude. Let the hypotenuse S C, the comet's distance from the Sun, be sought in this way. The sum of the antilogarithms of the two sides is the antilogarithm of the distance sought. This holds, however, on the express condition that the longitude of the Sun and the longitude of the comet lie in one and the same quadrant; or indeed in different

[174] the sixth line is labelled "Long. ang." on the page, where the other calculations print "Log. ang.". No "Bor." stands below the declination in this calculation.

[175] no "Bor." stands below the declination in this calculation.

quadrants, provided that the difference of the longitudes does not exceed 90 degrees. But if the difference between the Sun and the comet exceeds 90, or 180, or 270 degrees, then one must use quite different rules, according as the longitude of the Sun is found in one quadrant or another with respect to the longitude of the comet. Sometimes this calculation is carried out by logarithms alone, as appears in our first example, where the longitude of the Sun lies in the third quadrant and that of the comet in the first. But when the place of the Sun is given in the fourth quadrant and that of the comet likewise in the first, as in all the remaining examples that follow, except the single preceding one, then the antilogarithm of the latitude is to be added to the logarithm of the difference of the longitudes of the comet and the Sun. The sum will be an antilogarithm whose arc is to be subtracted from the semicircle, so that the distance itself between the Sun and the comet results.

Diagram. A circle within a rectangular plate mark, set to the left of the narrow column of text. A great arc runs from E at the upper right of the rim, through the upper comet C and through B, down to F at the foot of the rim; it is labelled "Latitudinis." along its upper part and "Circuli" along its lower part (circle of latitude). The ecliptic, labelled "Ecliptica.", runs from D on the left rim through B to the small circle of the Sun near A on the right rim. Two comets are drawn, each as a small circle with a hatched tail: an upper one beside the letter C, with "Comet" along its tail, and a lower one on the left rim, with C below it and "Cometa" along its tail. From each comet a line runs to the Sun, labelled "Diſtant. Com. à Sole." along the upper line and "Diſt Com à Sole." along the lower (distance of the comet from the Sun). Above the Sun stands S, below it "Sol." (the Sun), and beyond it A on the rim. "Colurus" stands at the upper left of the rim and "Solſtitiorum." along the right rim (the solstitial colure). Below the circle, at the right, stands the engraver's note "Autor Sculps." (the author engraved it).

- E (upper right, on the rim, end of the circle of latitude)
- "Colurus" (upper left of the rim)
- "Comet" (along the tail of the upper comet; the word runs into the comet's head and no further letter is visible)
- C (beside the upper comet)
- "Latitudinis." (along the arc from C toward E)
- "Solſtitiorum." (along the right rim)
- D (left, on the rim, end of the ecliptic)
- B (where the circle of latitude crosses the ecliptic)
- "Diſtant. Com. à Sole." (along the line from the upper comet to the Sun)
- "Cometa" (along the tail of the lower comet)
- "Ecliptica." (along the ecliptic)
- C (below the lower comet)
- "Diſt Com à Sole." (along the line from the lower comet to the Sun)
- S (above the Sun)
- "Sol." (below the Sun)

- A (right, on the rim, beyond the Sun)
- "Circuli" (along the lower part of the arc toward F)
- F (foot of the rim)
- "Autor Sculps." (below the circle, at the right)

Observation 1 [Obſervatio 1.]

On December 20, at 7^h in the evening: the distance between the Sun and the comet sought.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	269° 39′ 12″			
Complement to 3 quadrants	20′ 48″			
Longitude of the comet	68° 24′ 24″			
Log. of the difference	68° 45′ 12″	7039		
Antil. of the comet's latitude *M.*	30° 49′ 1″	15221	*Add.*	
Logarithm		22260		36° 49′ 38″
Its complement to 180° is the distance sought				143° 10′ 22″

176

Observation 2 [Obſervatio 2.]

On December 23, at 7^h 22^m 7^s in the evening.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	272° 44′ 3″			
Excess over 3 quadrants	2° 44′ 3″

Northern latitude; its antil.	14° 11′ 39″	3101	*A.*	
Antilog.		32661		43° 49′ 54″
Its complement to 180° is the distance sought				136° 10′ 6″

Observation 16 [Obſervatio 16.]

On December 27, at 1^{h} 24^{m} 45^{s} in the morning.

[179] the complement is printed 136° 27′ 8″; 180° − 43° 32′ 42″ gives 136° 27′ 18″.
[180] the difference is printed 48° 38′ 57″; 54° 40′ 30″ − 6° 1′ 53″ gives 48° 38′ 37″.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	276° 3′ 25″			
Excess over 3 quadrants	6° 3′ 25″			
Longitude of the comet	54° 10′ 12″			
Difference; its log.	48° 6′ 47″	29510		
Northern latitude; its antil.	14° 41′ 24″	3323	*A.*	
Antilog.		32833		43° 56′ 6″
Its complement to 180 is the distance sought				136° 3′ 54″

Observation 17 [Obſervatio 17.]

On December 27, at 2^h 6^m 0^s in the morning.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	276° 5′ 12″			
Excess over 3 quadrants	6° 5′ 12″			
Longitude of the comet	54° 17′ 39″			
Difference; its log.	48° 12′ 27″	29362		
Northern latitude; its antil.	13° 53′ 14″	2966	*A.*	
Antilog.		32328		43° 38′ 0″
Its complement to 180° is the distance sought				136° 22′ 0″

Observation 18 [Obſervatio 18.]

On December 27, at 5^h 14^m 5^s in the evening.

Line	Value	Loga-rithm	Mark	Result
Longitude of the Sun	276° 43′ 51″			
Excess over 3 quadrants	6° 43′ 51″			
Longitude of the comet	53° 15′ 27″			
Difference; its log.	46° 31′ 36″	32061		
Northern latitude; its antil.	16° 1′ 22″	3962	*A.*	
Antilog.		36023		45° 46′ 20″
Its complement to 180° is the distance sought				134° 13′ 40″

Observation 19 [Obſervatio 19.]

On December 27, at 5^h 19^m 1^s in the evening.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	276° 44′ 4″			
Excess over 3 quadrants	6° 44′ 4″			
Longitude of the comet	53° 34′ 51″			
Difference; its log.	46° 50′ 47″	31535		
Northern latitude; its antil.	16° 2′ 31″	3972	*A.*	
Antilog.		35507		45° 28′ 58″

Line	Value	Logarithm	Mark	Result
Its complement to 180° is the distance sought				134° 31′ 2″

Observation 20 [Obſervatio 20.]

On December 27, at 5^{h} 23^{m} 58^{s} in the evening.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	276° 44′ 15″			
Excess over 3 quadrants	6° 44′ 15″			
Longitude of the comet	53° 39′ 26″			
Difference; its log.	46° 55′ 11″	31416		
Northern latitude; its antil.	16° 13′ 43″	4066	*A.*	
Antilog.		35482		45° 28′ 8″
Its complement to 180° is the distance sought				134° 31′ 52″

Observation 21 [Obſervatio 21.]

On December 27, at 5^{h} 33^{m} 39^{s} in the evening.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	276° 44′ 41″			
Excess over 3 quadrants	6° 44′ 41″			
Longitude of the comet	53° 58′ 30″			
Difference; its log.	47° 13′ 49″	30914		
Northern latitude; its antil.	16° 5′ 34″	3997	*A.*	
Antilog.		34911		45° 8′ 40″
Its complement to 180° is the distance sought				134° 51′ 20″

Observation 22 [Obſervatio 22.]

On December 27, at 5^{h} 38^{m} 10^{s} in the evening.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	276° 46′ 6″			
Excess over 3 quadrants	6° 46′ 6″			
Longitude of the comet	53° 58′ 10″			
Difference; its log.	47° 12′ 4″	30959		
Northern latitude; its antil.	16° 11′ 56″	4051	*A.*	
Antil.		35010		45° 12′ 4″
Its complement to 180° is the distance sought				134° 47′ 54″

181

[181]the complement is printed 134° 47′ 54″; 180° − 45° 12′ 4″ gives 134° 47′ 56″.

Observation 23 [Obſervatio 23.]

On December 27, at 5^h 40^m 48^s in the evening.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	276° 45′ 0″			
Excess over 3 quadrants	6° 45′ 0″			
Longitude of the comet	53° 52′ 20″			
Difference; its log.	47° 7′ 20″	31088		
Northern latitude; its antil.	16° 12′ 25″	4055	*A.*	
Antilog.		35143		45° 16′ 36″
Its complement to 180° is the distance sought				134° 43′ 24″

182

Observation 24 [Obſervatio 24.]

On December 27, at 5^h 50^m 9^s in the evening.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	276° 45′ 24″			
Excess over 3 quadrants	6° 45′ 24″			
Longitude of the comet	53° 34′ 26″			
Difference; its log.	46° 49′ 2″	31581		
Northern latitude; its antilog.	16° 21′ 14″	4130	*A.*	
Antilogarithm		35711		45° 35′ 50″
Its complement to 180° is the distance sought				134° 24′ 10″

Observation 25 [Obſervatio 25.]

On December 27, at 11^h 44^m 31^s in the evening.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	277° 0′ 27″			
Excess over 3 quadrants	7° 0′ 27″			
Longitude of the comet	53° 23′ 24″			
Difference; its log.	46° 22′ 57″	32300		
Northern latitude; its antil.	17° 5′ 57″	4520	*A.*	
Antilogarithm		36820		46° 12′ 28″
Its complement to 180° is the distance sought				133° 47′ 32″

[182] the first label is printed "Longit. Sobis".

Observation 26 [Obſervatio 26.]

On December 27, at 11^h 52^m 31^s in the evening.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	277° 0′ 49″			
Complement to 3 quadrants	7° 0′ 49″			
Longitude of the comet	53° 13′ 36″			
Log. of the difference	46° 12′ 47″	32583		
Northern latitude; its antil.	17° 1′ 32″	4482	*A.*	
Logarithm		37065		46° 20′ 52″
Its complement to 180° is the distance sought				133° 39′ 8″

183

Observation 27 [Obſervatio 27.]

On December 28, at 12^h 13^m 46^s in the morning.

Line	Value	Loga-rithm	Mark	Result
Longitude of the Sun	277° 1′ 43″			
Excess over 3 quadrants	7° 1′ 43″			
Longitude of the comet	53° 14′ 19″			
Difference; its log.	46° 13′ 36″	32560		
Northern latitude; its antil.	17° 6′ 7″	4522	*A.*	
Antilogarithm		37082		46° 21′ 24″
Its complement to 180° is the distance sought				133° 38′ 36″

184

Observation 28 [Obſervatio 28.]

On December 28, at 1^h 34^m 10^s in the morning.

Line	Value	Loga-rithm	Mark	Result
Longitude of the Sun	277° 5′ 10″			
Excess over 3 quadrants	7° 5′ 10″			
Longitude of the comet	53° 24′ 50″			
Difference; its log.	46° 19′ 40″	32390		
Northern latitude; its antil.	17° 10′ 50″	4564	*A.*	
Antilog.		36954		46° 17′ 12″
Its complement to 180° is the distance sought				133° 42′ 48″

[183] the second line is labelled "Complem. ad 3 quad." (complement to 3 quadrants), although its figure is the excess of the Sun's longitude over 270°, as in the other calculations of this kind.

[184] the difference is printed 46° 13′ 36″; 53° 14′ 19″ − 7° 1′ 43″ gives 46° 12′ 36″.

Observation 29 [Observatio 29.]

On December 29, at 3^h 50^m 52^s in the morning.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	278° 12′ 18″			
Excess over 3 quadrants	8° 12′ 18″			
Longitude of the comet	51° 40′ 33″			
Difference; its log.	43° 28′ 15″	37399		
Northern latitude; its antil.	20° 20′ 28″	6439	*A.*	
Antilog.		43838		49° 49′ 40″
Its complement to 180° is the distance sought				130° 10′ 20″

Observation 30 [Observatio 30.]

On December 29, at 3^h 55^m 52^s in the morning.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	278° 12′ 33″			
Excess over 3 quadrants	8° 12′ 33″			
Longitude of the comet	51° 25′ 58″			
Difference; its log.	43° 13′ 25″	37857		
Northern latitude; its antil.	20° 13′ 28″	6364	*A.*	
Antilogarithm		44221		50° 0′ 45″
Its complement to 180° is the distance sought				129° 59′ 15″

Observation 31 [Observatio 31.]

On December 29, at 4^h 5^m 50^s in the morning.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	278° 15′ 3″			
Excess over 3 quadrants	8° 15′ 3″			
Longitude of the comet	52° 32′ 39″			
Difference; its log.	44° 17′ 36″	35906		
Northern latitude; its antil.	19° 55′ 21″	6171	*A.*	
Antilog.		42077		48° 57′ 45″
Its complement to 180° is the distance sought				131° 2′ 15″

Observation 32 [Observatio 32.]

On December 29, at 4^h 28^m 50^s in the morning.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	278° 13′ 55″			

Line	Value	Logarithm	Mark	Result
Excess over 3 quadrants	8° 13′ 55″			
Longitude of the comet	52° 56′ 37″			
Difference; its log.	44° 42′ 42″	35163		
Northern latitude; its antil.	19° 23′ 14″	5837	*A.*	
Antilog.		41000		48° 25′ 18″
Its complement to 180° is the distance sought				131° 34′ 42″

Observation 33 [Obſervatio 33.]

On December 29, at 4^{h} 47^{m} 49^{s} in the morning.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	278° 14′ 44″			
Excess over 3 quadrants	8° 14′ 44″			
Longitude of the comet	51° 28′ 3″			
Difference; its log.	43° 13′ 19″	37860		
Northern latitude; its antil.	20° 7′ 37″	6301	*A*	
Antilog.		44161		49° 59′ 3″
Its complement to 180° is the distance sought				130° 0′ 57″

Observation 34 [Obſervatio 34.]

On December 29, at about 5^{h} in the morning.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	278° 16′ 25″			
Excess over 3 quadrants	8° 16′ 25″			
Longitude of the comet	52° 21′ 35″			
Difference; its log.	44° 5′ 10″	36278		
Northern latitude; its antil.	20° 32′ 44″	6572	*A.*	
Antilog.		42850		49° 20′ 43″
Its complement to 180° is the distance sought				130° 39′ 17″

Observation 35 [Obſervatio 35.]

On December 30, at 6^{h} 10^{m} 30^{s} in the evening.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	279° 50′ 12″			
Excess over 3 quadrants	9° 50′ 12″			
Longitude of the comet	51° 27′ 48″			
Difference; its log.	41° 37′ 36″	40908		
Northern latitude; its antil.	23° 23′ 17″	8573	*A.*	

Line	Value	Logarithm	Mark	Result
Antilog.		49481		52° 26′ 0″
Its complement to 180° is the distance sought				127° 34′ 0″

Observation 36 [Obſervatio 36.]

On December 31, at 3^h 37^m 26^s in the morning.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	280° 14′ 9″			
Excess over 3 quadrants	10° 14′ 9″			
Longitude of the comet	51° 14′ 22″			
Difference; its log.	4° 0′ 13″	42142		
Northern latitude; its antil.	23° 58′ 19″	9020	*A.*	
Antilog.		51162		53° 9′ 55″
Its complement to 180 is the distance sought				126° 50′ 5″

185

Observation 37 [Obſervatio 37.]

On December 31, at 3^h 44^m 24^s in the morning.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	280° 14′ 27″			
Excess over 3 quadrants	10° 14′ 27″			
Longitude of the comet	51° 18′ 48″			
Difference; its log.	41° 4′ 21″	42004		
Northern latitude; its antil.	23° 48′ 51″	8897	*A.*	
Antilog.		52901		53° 3′ 9″
Its complement to 180° is the distance sought				126° 56′ 51″

186

Observation 38 [Obſervatio 38.]

On December 31, at 4^h 7^m 18^s in the morning.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	280° 15′ 48″			
Excess over 3 quadrants	10° 15′ 48″			

[185] the degrees of the difference are printed as the single figure 4; 51° 14′ 22″ − 10° 14′ 9″ gives 41° 0′ 13″.

[186] the summed antilogarithm is printed 52901; 42004 + 8897 gives 50901.

Line	Value	Logarithm	Mark	Result
Longitude of the comet	51° 28′ 40″			
Difference; its log.	41° 12′ 52″	41722		
Northern latitude; its antil.	24° 3′ 3″	9082	*A.*	
Antilog.		50804		53° 0′ 40″
Its complement to 180° is the distance sought				126° 59′ 20″

Observation 39 [Obſervatio 39.]

On December 31, at 4^{h} 27^{m} 22^{s} in the morning.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	280° 16′ 18″			
Excess over 3 quadrants	10° 16′ 18″			
Longitude of the comet	51° 4′ 0″			
Difference; its log.	40° 47′ 42″	42562		
Northern latitude; its antil.	24° 16′ 40″	9259	*A.*	
Antilog.		51821		53° 26′ 41″
Its complement to 180° is the distance sought				126° 33′ 19″

Observation 40 [Obſervatio 40.]

On January 1, in the year 1653, at 2^{h} 15^{m} 40^{s} in the morning.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	281° 12′ 14″			
Excess over 3 quadrants	11° 12′ 14″			
Longitude of the comet	51° 14′ 12″			
Difference; its log.	40° 1′ 58″	44125		
Northern latitude; its antil.	25° 31′ 57″	10277	*A.*	
Antilog.		54402		54° 31′ 15″
Its complement to 180° is the distance sought				125° 28′ 45″

Observation 41 [Obſervatio 41.]

On January 1, at 2^{h} 20^{m} 43^{s} in the morning.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	281° 12′ 25″			
Excess over 3 quadrants	11° 12′ 25″			
Longitude of the comet	50° 59′ 47″			
Difference; its log.	39° 47′ 22″	44633		
Northern latitude; its antil.	25° 43′ 53″	10441	*A.*	
Antilog.		55074		54° 47′ 37″

Line	Value	Logarithm	Mark	Result
Its complement to 180° is the distance sought				125° 12′ 23″

Observation 42 [Obſervatio 42.]

On January 1, at 2^h 24^m 55^s in the morning.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	281° 12′ 35″			
Excess over 3 quadrants	11° 12′ 35″			
Longitude of the comet	50° 53′ 10″			
Difference; its log.	39° 40′ 35″	44870		
Northern latitude; its antil.	25° 50′ 48″	10538	*A.*	
Antil.		55408		54° 55′ 41″
Its complement to 180° is the distance sought				125° 4′ 19″

Observation 43 [Obſervatio 43.]

On January 1, at 2^h 52^m 49^s in the morning.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	281° 13′ 46″			
Excess over 3 quadrants	11° 13′ 46″			
Longitude of the comet	50° 55′ 29″			
Difference; its log.	39° 41′ 43″	44830		
Northern latitude; its antil.	25° 44′ 43″	10453	*A.*	
Antilog.		55283		54° 52′ 40″
Its complement to 180° is the distance sought				125° 7′ 20″

Observation 44 [Obſervatio 44.]

On January 1, at 3^h 3^m 48^s in the morning.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	281° 14′ 14″			
Excess over 3 quadrants	11° 14′ 14″			
Longitude of the comet	50° 56′ 21″			
Difference; its log.	39° 42′ 7″	44817		
Northern latitude; its antilog.	25° 46′ 12″	10475	*A.*	
Antilogarithm		55292		54° 52′ 53″
Its complement to 180° is the distance sought				125° 7′ 7″

Observation 45 [Obſervatio 45.]

On January 1, at 3^h 3^m 48^s in the morning.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	281° 14′ 14″			
Excess over 3 quadrants	11° 14′ 14″			
Longitude of the comet	50° 55′ 24″			
Difference; its log.	39° 41′ 10″	44850		
Northern latitude; its antil.	25° 44′ 25″	10449	*A.*	
Antilogarithm		55299		54° 53′ 4″
Its complement to 180° is the distance sought				125° 6′ 56″

Observation 46 [Obſervatio 46.]

On January 1, at 3^h 26^m 0^s in the morning.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	281° 15′ 12″			
Complement to 3 quadrants	11° 15′ 12″			
Longitude of the comet	50° 44′ 45″			
Log. of the difference	39° 29′ 33″	45259		
Northern latitude; its antil.	25° 49′ 51″	10525	*A.*	
Logarithm		55784		55° 4′ 44″
Its complement to 180° is the distance sought				124° 55′ 16″

187

Observation 47 [Obſervatio 47.]

On January 1, at 3^h 44^m 16^s in the morning.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	281° 15′ 58″			
Excess over 3 quadrants	11° 15′ 58″			
Longitude of the comet	50° 43′ 42″			
Difference; its log.	39° 27′ 44″	45323		
Northern latitude; its antil.	25° 49′ 58″	10527	*A.*	
Antilogarithm		55850		55° 6′ 20″
Its complement to 180° is the distance sought				124° 53′ 40″

[187] as in Observation 26, the second line is labelled "Complem. ad 3 quad." (complement to 3 quadrants), although its figure is the excess of the Sun's longitude over 270°.

Observation 48 [Obſervatio 48.]

On January 2, at 6^h 27^m 30^s in the evening.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	282° 54′ 53″			
Excess over 3 quadrants	12° 54′ 53″			
Longitude of the comet	50° 28′ 0″			
Difference; its log.	37° 33′ 7″	49477		
Northern latitude; its antil.	27° 9′ 0″	11674	*A.*	
Antilog.		61151		57° 8′ 36″
Its complement to 180° is the distance sought				122° 51′ 24″

Observation 49 [Obſervatio 49.]

On January 3, at 6^h 47^m 30^s in the evening.

Line	Value	Logarithm	Mark	Result
Longitude of the Sun	283° 57′ 1″			
Excess over 3 quadrants	13° 57′ 1″			
Longitude of the comet	50° 10′ 41″			
Difference; its log.	36° 13′ 40″	52593		
Northern latitude; its antil.	29° 2′ 40″	13441	*A.*

Having thus computed the comet's longitudes and latitudes, declinations and right ascensions, and also its elongations from the Sun, by means both of the altitudes and azimuths and of the distances, it will also be worthwhile to gather all of them into a single table, so that the apparent place of the comet on any day may be more readily available to anyone.

A table showing the place of the comet, both with respect to the ecliptic and the equator, and its distance from the Sun.

Year 1652; day	Corrected time	Longitude	Sign	Latitude	Mark	Declination	Mark	Right ascension	Distance of the comet from the Sun

188

[188] the table is framed and ruled; a rule stands under the headings and under every third row. The first column is headed with the year 1652 and "Die" (day), the time column "corrected time" in hours, minutes and seconds, and each angle column in degrees, minutes and seconds. The last column carries no heading; "From the distances" renders its entry "Ex diſtant.". In the time column *v.* and *m.* stand after the figures. The sign column stands beside the longitude, marked by the "S." of its heading "Gr Min Sec.S."; each sign and each latitude and declination mark is printed only in some rows, as shown, and a blank sign or mark cell is blank on the page. The declination and right ascension of the second observation at $3^h\ 3^m\ 48^s$ on January 1 are blank on the page. The year 1653 is printed in the first column of the last December 31 row.

Section IX. To Investigate the Comet's Proper and Daily Motion, both the Relation It Held to the Equator, or the Angle between the Equator and the Comet's Orbit, and the Node, or Point of Intersection with the Equator [SECTIO IX. Motum Cometæ proprium & diurnum, tùm rationem, quàm ad Æquatorem obtinuerit, ſive angulum Æquatoris & Orbitæ Cometalis, tùm Nodùm, ſeu punctum interſectionis Æquatoris indagare.]

From the calculation carried out above at length and with care, it is very clear that our comet continually changed not only its declinations and right ascensions with respect to the equator, but also its longitudes and latitudes with respect to the ecliptic. It did so in such a way that in longitude it advanced gradually, against the order of the signs, while in latitude it advanced with a fairly swift motion, roughly towards the north, crossing the equator and the ecliptic at a certain angle of inclination.

[Margin: Cometa motui proprio obnoxius fuit.] (The comet was subject to a proper motion.)

Since it is therefore more than certain that the comet had a proper motion [motus proprius] in a particular orbit, it will also be our task to examine that motion — both the angle between the comet's orbit and the equator and the point of their intersection — with the utmost diligence, as is fitting. Before we come to that, however, we shall first set out the demonstration and the method of the calculation, so that afterwards it will be necessary to give only the bare calculation. From which observations, and in what order, we sought the daily motion, the calculation itself will show.

[Margin: Ex quibus obſervationibus motus proprius nec non angulus orbitæ exquiſitùs eruatur?] (From which observations are the proper motion and also the angle of the orbit derived most precisely?)

We have taken care that the comet's proper motion, the angle of the orbit and the point of intersection should be derived from observations and from more distant places of the comet (from which this can be done far more certainly): above all, that is, from the observation made on December 20, the first day of the apparition, at about 7 in the evening, when the comet formed an equilateral triangle with fixed stars. For from places separated from one another by no notable distance, all these quantities are computed hardly accurately enough, because the angles are too acute.

In the figure shown here, let ACEBD be the meridian, AB the equator, E its pole, EI, EK and EL circles of declination, and DHC the comet's orbit, intersecting the equator at H. Let M be the comet's place on December 20, and G its place on December 23, so that LM and IG are the comet's declinations, and AI and AL the right ascensions. With the diagram drawn in this way, MG is the proper motion that the comet completed in its orbit within the space of those days, namely from December 20 to December 23; MHL, or IHG, is the angle between the comet's orbit and the ecliptic; and H is the point of intersection. These three must now be examined by this method.

Diagram. An engraved figure set beside the text: a circle (the meridian of the text) with E at its top, B at the left and A at the right ends of a line labelled "Equator". A straight line from D at lower left to C at upper right is labelled "Orbit" near D and "of the comet" near C, the two words together reading "orbit of the comet"; on it stand M, H, G and F, in that order from D. From E three curves descend to the equator: one through O and L, labelled "Circle of declination", continuing to M below the equator; one through N to I; and one through F to K, labelled "Circle of declination" (its two words set one above the other along the curve). Dotted lines join N to F and O to G. At the lower right, outside the circle, is the engraver's signature "Autor Sculps." (the author engraved it).

- E (top of the circle): point
- C (upper right, on the circle): point
- N (on the curve from E to I): point
- F (on the orbit line and the curve from E to K): point
- O (on the curve from E to L): point
- G (on the orbit line and the curve from E to I): point
- B (left end of the equator line): point
- A (right end of the equator line): point
- L (on the equator line, left): point
- H (on the equator line, where the orbit line crosses it): point
- I (on the equator line, centre): point
- K (on the equator line, right of I): point
- M (on the orbit line, below the equator): point
- D (lower left, on the circle): point
- *Circ. Declinat.* (along the curve E–O–L–M): circle of declination
- *Declin* and *Circul.* (along the curve E–F–K, upper and lower): circle of declination
- *Cometæ.* and *Orbita* (along the line D–C, upper and lower): orbit of the comet
- *Æquator.* (below the equator line, right of K): equator
- *Autor Sculps.* (lower right): the author engraved it

1. In the triangle EGO, right-angled at O, let the perpendicular GO be sought from IL, the difference of the comet's right ascensions, which determines the angle E, and from EG, the complement of the comet's declination at the later station, by this rule: the sum of the logarithms of the two given quantities is the logarithm of the side sought.
2. In the same triangle, from the same hypotenuse and the perpendicular just found, you will find the third side EO. That is, if you subtract the antilogarithm of GO from the antilogarithm of EG, the remainder will be the antilogarithm of the side EO sought. Taking EO from EM, the comet's distance from the pole at the observation [phænomeni] of December 20, you will have OM.

3. Now in the smaller triangle GOM let the hypotenuse GM be computed — that is, the comet's proper motion between December 20 and 23 — the two sides about the right angle, GO and MO, being given. Accordingly, the sum of the antilogarithms of the two sides will be the antilogarithm of the proper motion MG.

[Margin: Ratio calculi pro ſupputando motu proprio.] (Method of calculation for computing the proper motion.)

4. In the triangle MOG just mentioned, let the angle HML likewise be found, the two sides GO and MG being given: subtracting the logarithm of the hypotenuse GM from the logarithm of the side GO, there will remain the logarithm of the angle HML sought.
5. To find the angle between the orbit and the equator, there are given in the triangle LMH the comet's latitude LM on December 20 and the angle HML found above. From these the angle LHM, or IHG, is derived, which as a vertical angle is equal to the former, by Theorem 8, Proposition 15, of Book I of Euclid (Euclid, *Elements* I.15). That is, if you add the logarithm of HML to the antilogarithm of LM, the latitude, the antilogarithm of the angle LHM, or IHG, sought will result.
6. Finally, to compute the point of intersection H, that is, of the orbit and the equator: in the triangle MLH there are given the angle MHL just found and the comet's latitude LM. Let the side HL therefore be found in this way: the sum (algebraic [cosſica], if need be) of the logarithm of the side LM and the mesologarithm of the angle HML is the mesologarithm of the side HL sought. In this case this side is subtracted from the comet's right ascension L of the 20th, so as to obtain the point H, as is clear from the preceding diagram and from the following calculation.

Calculation of the daily motion, of the angle between the comet's orbit and the equator, and also of their point of intersection.

[189] left column of the calculation. On the page the two dated captions stand side by side over the first two lines, which carry the two stations' values side by side, as set above. The angle values stand in one column at the right of the logarithms; the value of GO, 19° 20′ 19″, is printed on the line of its logarithm. A row of degree, minute and second marks stands over the antilogarithm line of EO. Rules stand under the right ascension of December 26, under the log. of the angle IEL, under the antil. of GO, and under the distance EM.

[190] right column of the calculation. The notes "motus prop." (proper motion) and "Orb. & Æquat." (orbit and equator) each run over two lines at the right, beginning on the line shown. Rules stand under the antil. of GO, under the log. of GM, under the second log. of the angle HML, under the mesolog. of HML, and under the right ascension of December 20.

[193] the page is set in two columns, each holding two calculations one above the other: 10 above 11 at the left, 12 above 13 at the right. Each is laid out as the calculations of pp. 133–134, with the same rules; the notes read "motus proprius" (proper motion) and "Orbitæ & Æquat." or "Orb. & Æquat." (orbit and equator). On the mesolog. of HL each calculation here prints a mark "S." after the figures, not printed on that line on pp. 133–134. In calculations 11–13 the line of the right ascension of December 20 is headed "Longit." (longitude) in its second use, at the foot. In calculation 12 the two right ascensions carry no point letters, and the second figure of the minutes in the time of December 26 is read as 3 (an old-style 3, descending below the line), although the table on p. 136 prints the time of this observation as 11^h 38^m 22^s. The lower part of the page is blank.

194

Why, my reader, did we see fit to investigate, so many times, both the angle between the equator and the comet's orbit and the point of intersection? And how large, moreover, was that angle in fact at that time? Since the calculations do not wholly agree with one another, we shall say in the next Section. At this point nothing more remains to be added except how large the comet's daily motion was, found from entirely different observations — namely, those made by altitudes and azimuths — so that that motion may likewise be explored the more surely, and also so that the proper motion found above by means of the distances may, as it were, be tested by it. For brevity's sake, however, let us omit the calculation itself, and only indicate, and show in a small table, from which observations and which data it was derived, and how large it came out. For everything was investigated by exactly the same method as before, except that in these examples both declinations were northern, namely IG and KF, as is

[194] the two calculations stand side by side at the head of the page, 14 at the left and 15 at the right, each laid out as the calculations of pp. 133–135, with the same rules; the note "motus prop." reads "motus propr." in calculation 15. Neither prints the mark "S." after the figures on the mesolog. of HL.

clear from the figure above, so that the proper motion is GF, and the difference of the right ascensions KI.

[Margin: Majoris certitudinis gratiâ, ex diverſis aliis obſervationibus motus Cometæ proprius exploratus eſt.] (For greater certainty, the comet's proper motion has been explored from various other observations.)

195

[195] the table is ruled in a double frame. Its group heads are "Obſervationes." (observations) over the day, month and time, "Data." over the declination and right ascension, and "Quæſita." (sought) over the proper motion; the time column is headed "Sec. Horol.corr." (by the corrected clock), with "Hor.Min. Sec." under it, and the declination and right ascension "Gr.Min.Sec.". The rows stand in pairs, each the observation of December 23 and a later one; a brace joins the two right ascensions of each pair, and the proper motion of each pair is set once, centred between its two rows (given here on the first row). In the third pair the first declination is followed by "B," with a comma. No labels stand below the last row.

Section X. Given the Comet's Longitudes and Latitudes, to Find Its Proper and Daily Motion, and Also the Relation It Had to the Ecliptic, That Is, the Angle of the Comet's Orbit and the Ecliptic, and Also the Node, or Its Point of Intersection [SECTIO X. Datis Cometæ Longitudinibus & Latitudinibus, motum ejus proprium, & diurnum, tùm rationem quàm ad Eclipticam obtinuerit, ſive angulum orbitæ Cometalis & Eclipticæ, tùm Nodum, ſeu punctum ejus interſectionis indagare.]

Since this calculation rests on exactly the same demonstration and method of computation as the preceding one, and likewise on the rules of logarithms, there is no need to repeat it all again. It will therefore be enough if we add only a description of the accompanying figure, which serves this investigation, and also set briefly before the eyes, as if in a small table, the order in which the triangles are solved. Let ACEBDE, then, be the solstitial colure [colurus Solstitiorum], AB the ecliptic, and E its pole; the arcs descending from E, namely EL, EI and EK, the circles of latitude; DHC the orbit of the comet, so that F, G, G is the comet's place; H the point of intersection with the ecliptic, or node; AL, AI and AK the longitudes; and KF, IG and LG the latitudes; while the angle IHG, or LHG, is the angle of the comet's orbit and the ecliptic, and GF the proper motion.

[Margin: Simili planè ratione Cometæ ſitus ad Eclipticam, ut ad Æquatorem ſupputatur.] (The comet's position with respect to the ecliptic is computed in exactly the same way as with respect to the equator.)

Diagram. An engraved figure set beside the text: a circle, the solstitial colure, labelled "Colurus" inside it at the upper left and "Solstitiorum." along its right side. On the circle stand E at the upper right, C just below and to the right of it, B at the left, D at the lower left, A at the lower right and a second E at the bottom. A straight line from B to A is labelled "Ecliptica." (ecliptic); on it stand K, I and H, in that order from B, and L beyond H. A straight line from D to C is labelled "Orbita" (orbit) near D and "Cometæ." (of the comet) near C; on it stand F, a lower G and an upper G, and it crosses the ecliptic at H. From the upper E a curve labelled "Circ. Latit" (circle of latitude) descends through the upper G to L. From the lower E two curves rise, labelled "Circ. Latit." and "Circ. Latitud." (circle of latitude): one through F to K, the other through N and the lower G to I. A dotted line joins F to N. At the lower right, inside the frame, is the engraver's signature "Autor sculps." (the author engraved it).

- E (upper right, on the circle): point
- C (on the circle, right of E): point
- B (left, on the circle; end of the ecliptic): point
- D (lower left, on the circle; end of the orbit line): point
- A (lower right, on the circle; end of the ecliptic): point
- E (bottom of the circle): point
- K, I, H (on the ecliptic, in order from B): points
- L (on the ecliptic, beyond H): point
- G (upper, on the orbit line and the curve from the upper E): point

- G (lower, on the orbit line and the curve through N): point
- F (on the orbit line and the curve to K): point
- N (on the curve to I, joined to F by a dotted line): point
- *Colurus* and *Solstitiorum.* (inside the circle, upper left and right side): solstitial colure
- *Ecliptica.* (below the ecliptic line, right): ecliptic
- *Orbita* and *Cometæ.* (along the line D–C, lower and upper): orbit of the comet
- *Circ. Latit* (along the curve from the upper E): circle of latitude
- *Circ. Latit.* and *Circ. Latitud.* (along the two curves from the lower E): circle of latitude
- *Autor sculps.* (lower right): the author engraved it

But in what order is the calculation to be undertaken, which triangles are to be solved, from which data, and what is sought? The following small table shows it. It should be noted, however, that in this calculation the comet's longitudes must always be used in place of the right ascensions, and its latitudes in place of the declinations, as is easy to gather. Moreover, since in our first example below both latitudes are southern, the figure takes on an entirely different appearance; and so, as a consequence, entirely different triangles also arise to be solved, as you see.

Right triangles to be solved	Given	Sought
1 Triangle ENF	Angle NEF, difference of longitude IK Side EF, complement of the latitude of the earlier day	perpendicular FN
2 Triangle ENF	Hypotenuse EF, complement of the latitude perpendicular FN, just found	Side EN; when this is subtracted from EG, the complement of the latitude, there remains side NG
3 Triangle GNF	Side NG Side FN, perpendicular	proper motion GF

196

[Margin: Compendioſa calculi ratio.] (A short method of calculation.)

Right triangles to be solved	Given	Sought
4 Triangle GNF	Side FN	Angle NGH, or HGI, which is equal to the one found

[196] an unruled scheme: the two lines of given data for each triangle are enclosed in square brackets, and the sought quantity stands to the right of them, centred between the two lines. In the second triangle EN stands over EG with a rule beneath, and NG below the rule.

Right triangles to be solved	Given	Sought
	Hypotenuse FG, or the proper motion	
5 Triangle GIH	Side IG, latitude of the comet on the later day	Angle of the orbit and the ecliptic GHI,
	Angle HGI, just found	to which the vertical angle LHG is equal
6 Triangle GIH	Angle of the orbit and the ecliptic GHI	Side IH
	Side IG, latitude of the comet	Let it be subtracted from AI, the comet's longitude on December 23
		There remains H, the point of intersection of the orbit and the ecliptic

197

The angle of the orbit and the ecliptic can, however, also be found by another method (as we have in fact done in certain examples), especially when the comet's latitude on one of the two days is too slight; for then the angle is found less accurately by the method described above than by the following one given here. First, let side HI be added to the difference of longitude IK, if the point of intersection precedes or follows both of the comet's longitudes; but if that point falls between the comet's two longitudes, let it be subtracted, so that HK results. Then in triangle FKH, given KF, the comet's latitude on December 20, and HK, the hypotenuse HF is found — namely the distance the comet travelled from the first day of its appearance, December 20 at 7^{h}, up to its very intersection with the ecliptic — that is, from the logarithm made up by the sum of the antilogarithms of the sides KF and HK. Next, with the hypotenuse HF and the opposite side KF thus known, you will find the required angle of the orbit and the ecliptic, FHK or LHG, from the remainder, as it were, of the logarithms of HF and KF.

Finally, I would have you note about the former calculation that if the difference of longitude does not exceed 4 or 5 degrees but is smaller, then by no means are either the angle of the orbit or the point of intersection derived correctly enough, however great the diligence with which the observation was made. Observations should therefore be chosen in which neither too acute angles nor too small sides occur; otherwise, as we have said, all the labour will be in vain. For this reason too, in certain examples we contented ourselves with the comet's proper motion, omitting both the angle of the orbit and the ecliptic and the point of intersection. On the same ground, likewise, some angles of the orbit and the ecliptic, and certain points of intersection (as will be clear from the examples that follow), which were drawn from too acute-angled triangles, seem in part to waver. But so that we may proceed the more safely in

[197]the scheme of p. 137 continues under its three heads, repeated at the top of this page, with the same square brackets. In the sixth triangle a rule stands under the line "Let it be subtracted…", and "There remains" and "H, the point of intersection…" stand below it.

this difficult business, and so that our computations may at the same time earn the greater trust, we have hunted for that angle and that point of intersection not once or twice, as others have mostly done, but thirty times and more, as is plain from the following calculation.

[Margin: Non promiſcuè ex omnibus obſerv. angulus orbitæ omninò accuratè inveſtigatur.] (The angle of the orbit is not found quite accurately from all observations indiscriminately.)

Calculation of the daily motion, of the angle of the comet's orbit and the ecliptic, and also of the point of intersection with the Sun's path

198

This was the method of demonstrating and computing the proper motion, etc., when, that is, both latitudes of the phenomenon are southern. Now, however, since in the following calculation the latitudes given are of different kinds — southern, namely, on the 20th, but northern on the 26th — a different figure is needed to demonstrate the calculation; for entirely different triangles arise to be solved, though exactly the same method of calculating by logarithms is kept. Let us therefore in turn set out briefly only the manner of the demonstration and of the solution (especially since the naming of the circles in the accompanying figure is wholly the same as above, except that M is the comet's place at the earlier observation and G at the later): first, what triangles are to be solved; second, from which data; and third, what is to be sought.

Diagram. An engraved figure set beside the text, drawn as that of p. 137 but for latitudes of different names: a circle, the solstitial colure, labelled "Colurus" inside it at the upper left and "Solstitiorum." along its right side. On the circle stand E at the top right, C to the right of it, B at the left, D at the lower left and A at the lower right. A straight line from B to A is labelled "Ecliptica." (ecliptic); on it stand L, H and I, in that order from B. A straight line from D to C is labelled "Orbita" (orbit) near D and "Cometæ." (of the comet) near C; on it stand M near D and G above the ecliptic, and it crosses the ecliptic at H. From E two curves descend: one labelled "Circul. Latit." (circle of latitude) through O and L to M; the other labelled "Circ. Latit." (circle of latitude) through G to I. A dotted line joins O to G. At the lower right, inside the frame, is the engraver's signature "Autor Sculps." (the author engraved it). No K, N or F is drawn.

[198] the two calculations stand side by side under the heading, the first at the left, the second (with the caption "Another way…" set within it) at the right, laid out as the calculations of the preceding pages, with rules under the figures that are added or subtracted. The marks after the figures of the right calculation's two logarithms and two mesologarithms are crosses. For the sides HI the page prints the minutes and seconds only, with no degree figure.

- E (top right, on the circle): point
- C (on the circle, right of E): point
- B (left, on the circle; end of the ecliptic): point
- D (lower left, on the circle; end of the orbit line): point
- A (lower right, on the circle; end of the ecliptic): point
- L, H, I (on the ecliptic, in order from B): points
- M (on the orbit line near D, end of the curve through O and L): point
- G (on the orbit line and the curve to I): point
- O (on the curve from E to M, joined to G by a dotted line): point
- *Colurus* and *Solstitiorum.* (inside the circle, upper left and right side): solstitial colure
- *Ecliptica.* (below the ecliptic line, right): ecliptic
- *Orbita* and *Cometæ.* (along the line D–C, lower and upper): orbit of the comet
- *Circul. Latit.* (along the curve E–O–L–M): circle of latitude
- *Circ. Latit.* (along the curve E–G–I): circle of latitude
- *Autor Sculps.* (lower right): the author engraved it

Right triangles to be solved	Given	Sought
1 Triangle GEO	Angle GEO, difference of longitude	GO, perpendicular
	Side EG, complement of the latitude of the comet	
2 Triangle GEO	Side EG, complement of the latitude of the comet	Side EO
	Side GO, perpendicular	EM, the comet's distance from the pole, is to be added
		Side OM
3 Triangle GOM	Side OM	Hypotenuse GM, namely the comet's proper motion
	Side GO, perpendicular	
4 Triangle GOM	Side GO, perpendicular	Angle HML
	Hypotenuse GM, proper motion	
5 Triangle HML	Latitude of the comet LM	Angle LHM of the comet's orbit and the ecliptic
	Angle HML, just found	
6 Triangle HML	Latitude of the comet LM	Side HL
	Angle HML	AL, longitude of the comet on the 20th; subtract
		H; there remains the point of intersection H

199

2.

[199] an unruled scheme set as that of pp. 137–138, with square brackets enclosing the two data lines of each triangle. In the second triangle EO stands over EM with a rule beneath, and OM below the rule; in the sixth, AL stands under HL and H under AL, with no rule.

[Margin: Cur tàm prolixisſimo calculo angulum orbitæ & Eclipticæ autor inveſtigatum iverit?] (Why did the author set out to investigate the angle of the orbit and the ecliptic with so very long a calculation?)

Almost to the point of nausea, in the judgement of some perhaps, we have sought by the calculation above both the angle of the orbit and the ecliptic, that is, the inclination, and the place of its intersection. Yet I do not regret

[208] the two calculations stand side by side, 34 on the left and 35 on the right, each laid out as the calculations of the preceding pages, with rules under the figures that are added or subtracted; the marks after the logarithm of LM and the two mesologarithms are crosses. Both take December 23, with the comet's southern latitude of 1° 43′ 23″, as the earlier day. In calculation 35 the first latitude is printed with no degree mark. Prose follows below them.

this labour, however extremely tedious, nor will you regret it, my Astrophile [Aſtrophile: lover of the stars, the reader]. For from the accurate investigation of this angle it is beyond all doubt that the said angle of the orbit and the ecliptic was not of the same size throughout the whole time of the apparition, as all the other observers whose writings I have chanced to see and read supposed. Rather, it changed continually from the comet's first rising right to its extinction, just as that point of intersection also did not always stay at the same place of the ecliptic: the comet's orbit cut the ecliptic gradually at one place after another.

[Margin: An angulus orbitæ Cometarum varietur?] (Whether the angle of the orbit of comets varies?)

So from this there arises a question of the greatest moment, one not yet brought into the open so far, let alone decided: namely, whether the angle of inclination, both of this comet and of all the others, was always unequal, or sometimes equal; and if it was subject to variation [recte: variationi], whether it increased continuously, or also sometimes decreased, and in what proportion this came about.

[Margin: An ex variatione anguli hujus, Cometæ neceſſariò in minori aliquo moveantur circulo?] (Whether, from the variation of this angle, comets necessarily move in some smaller circle?)

Further, if the angle of the orbit of comets and the ecliptic, or the equator, varies in this way from day to day, as will indeed become clear from what is to be said, it is rightly asked whether these phenomena move in a great circle, or in some smaller one; and whether it must be concluded infallibly from this that comets have notable parallaxes, and so move in the aerial region.

I admit, indeed, that at first sight it may seem to some, especially to anyone devoted to the Peripatetic school, that we have supplied an excellent and infallible argument for establishing the Peripatetics' opinion about comets. But I beg you to suspend your judgement until this matter is treated more fully. That can conveniently be done when the place of comets is discussed expressly in Book V, to which I also put off the questions just raised.

Now, however, let us return to our comet and inquire carefully how great and of what kind its proper motion was, both the daily motion for each single day and the hourly; likewise how large the angle of inclination to the ecliptic was, and how it varied from day to day, together with the place of intersection with the ecliptic, or node. So that this business may succeed the better, let us bring into a table both the proper motion and the said angle, together with the node, as found from the preceding calculation. In this way it will easily become clear what happened in this matter, and what we ought to conclude.

But I think I should first give notice here that both the proper motion and the angle of inclination, etc., were investigated not from observations of one kind only, namely from the comet's altitudes and azimuths, but equally also from those that rest on distances, and equally also from altitudes and distances taken together, for the sake of greater certainty. For in this way I was made the more certain of everything; and I noticed at last that while the proper motion

could be determined accurately from every calculation, the angle of the orbit, together with the node, could be determined best of all only from the distances; although, if you attend carefully, the results from the remaining observations scarcely differ even by one or two minutes. Therefore we have also given the first place in the following little table to these, namely to the results from the distances, even though they were not computed in that order.

The comet's proper motion, the angle of the orbit and the ecliptic, and also the place of its intersection.

[Margin: Ex Diſtantiis.] (From the distances.)

210

[Margin: Cometa motum peregit inæqualem initiò velociorem, in fine tardiorem.] (The comet performed an unequal motion, swifter at the beginning, slower at the end.)

It is therefore plainly apparent that the comet had not only a proper motion in its own orbit, inclined at a definite angle to the ecliptic and the equator, but also a motion wholly unequal from the beginning of its appearance to the end. This was such that around the beginning, namely on December 20, it had a very swift motion; afterwards one somewhat slackened from day to day; and toward the end a quite slow one. Yet this motion, however entirely different it was on each single day, was not therefore irregular. On the contrary, it kept the highest regularity in that inequality, continually decreasing, as this proper motion clearly testifies, if it is weighed more exactly, in the preceding table, and likewise in the following one, where it was derived from right ascensions and declinations. For, first, it is certain that from the 20th at about 7^h in the evening to the 23rd at $10^h\ 57^m\ 20^s$ it completed 30° 25′ 16″ in its course. Secondly, from the 23rd to the 26th at $11^h\ 38^m\ 22^s$[211] it completed 16° 2′, or at most 3′. Thirdly, from the 26th to December 30, again 10° 21′[212]. Fourthly, from the 30th to January 4, only 6° 21′. Fifthly and lastly, from January 4 to the 7th of the same month it travelled no more than 2° 12′. Since this is so, it necessarily follows, especially if the whole calculation is considered and examined more scrupulously, that our phenomenon kept, on each single day, such a proportion of daily motion as I show in the adjoining little table. The beginning of this motion is assumed to be counted from December 20 at $10^h\ 57^m\ 20^s$ in the evening, so that each day is taken as completed at $10^h\ 57^m\ 20^s$ in the evening.

The comet's daily motion in its orbit.

[210] the page sets the table of p. 149 again under its caption and the same column heads, as one framed table; double rules divide it into the three groups given here, each with its side-note in the left margin beside its first rows. Each row gives two days on two lines, the earlier above the later, with the three values once for the pair. The value columns are headed "Gr.Min.Sec." and the time column "Hor.Min.Sec."

[211] the page marks the 38 with a double stroke, like the 22.

[212] the page sets no minute mark after the 21.

Day of the month	Motion
20 December	0° 0′
21	11° 16′
22	9° 23′
23 December	7° 46′
24	6° 24′
25	5° 17′
26 December	4° 22′
27	3° 34′
28	2° 47′
29 December	2° 10′
30	1° 50′
31	1° 35′
1 January	1° 24′
2	1° 15′
3	1° 7′
4 January	1° 0′
5	0° 52′
6	0° 44′
7 January	0° 36′
8	0° 29′

[213]

[Margin: Vt ut Cometa inæqualem, tamen regularem motum exercuit.] (Although the comet performed an unequal motion, it was nonetheless regular.)

And so you see that from the 20th to the 21st the comet completed 11° 16′ in its path, but from the 21st to the 22nd only 9° 23′, and so on; so much so that its motion decreased day by day, keeping due proportion, and around its last appearance amounted to barely thirty minutes. From this we safely conclude that the motion of our star was continually direct, but decreasing; never, however, stationary, much less retrograde, in its own path, that is, as has indeed been detected in some comets by careful investigators of celestial things.

But to make the motion of this phenomenon still more evident, here, in the following little table, is its continuous course for the single days, likewise beginning from $10^h\ 57^m\ 20^s$. From it will be clear in what proportion it advanced day by day, and how great an arc of a great circle of its path it travelled in the whole time of its duration, namely from December 20 at 7^h in the evening to January 8 at 11^h in the evening: namely 65° 51″.

It will also be no less pleasant than useful, especially in the business of parallaxes, as you will find in due course, if these two little tables of motions of the daily kind, extended to the single hours, are presented by us. Therefore, to do our duty all the more in this respect, I did not wish to shirk this labour too.

[213] the table stands at the left of the prose, its figure columns headed "Grad." and "Min."; rules divide the rows into groups of three and a last group of two, and the month name stands only on the first row of each group.

The comet's proper and continuous motion, in the track of its circle.

Day of the month	Hours, minutes, seconds	Motion
20 December	$7^h\ 0^m\ 0^s$	0° 0′
20	$10^h\ 57^m\ 20^s$	2° 0′
21		13° 16′
22 December	$10^h\ 57^m\ 20^s$	22° 39′
23		30° 25′
24		36° 49′
25 December	$10^h\ 57^m\ 20^s$	42° 6′
26		46° 28′
27		50° 2′
28 December	$10^h\ 57^m\ 20^s$	52° 49′
29		54° 59′
30		56° 49′
31 December	$10^h\ 57^m\ 20^s$	58° 24′
1 January		59° 48′
2		61° 3′
3 January	$10^h\ 57^m\ 20^s$	62° 10′
4		63° 10′
5		64° 2′
6 January	$10^h\ 57^m\ 20^s$	64° 46′
7		65° 22′
8		65° 51′

214

But before we set these tables down here, let us present in one bundle that proper motion as derived from the declinations and right ascensions in the preceding section, together with the angle of inclination to the equator and the place of intersection. In this way it will at the same time be clear to anyone that we did not adopt this proportion of the daily and hourly motion rashly. For, as is evident, everything corresponds quite exactly, so that this motion scarcely ever departs, even by a single minute at most, from the earlier one computed from the longitudes and latitudes.

The comet's proper motion, the angle of the orbit and the equator, and also the place of its intersection.

[Margin: Ex Diſtantiis.] (From the distances.)

Day of the month	By the corrected clock	Proper motion	Angle of orbit and equator	Place of intersection, or node
20 December / 26 December	$7^h\ 0^m\ 0^s$ *v.* / $9^h\ 0^m\ 34^s$ *v.*	46° 10′ 2″	63° 0′ 44″	66° 53′ 29″

[214] the page sets this table in two halves side by side, the second half (from 28 December) with no caption or heads; rules divide the rows into groups of three, and the month name and the time stand only on the first row of each group (the first group gives two times). The heads read "Dies Menſ.", "Hor.Min.Sec." and "Grad.Min."

Day of the month	By the corrected clock	Proper motion	Angle of orbit and equator	Place of intersection, or node
20 December / 28 December	$7^h\ 0^m\ 0^s$ *v.* / $1^h\ 34^m\ 10^s$ *m.*	50° 6′ 6″	63° 0′ 22″	66° 53′ 25″
20 December / 29 December	$7^h\ 0^m\ 0^s$ *v.* / $4^h\ 55^m\ 32^s$ *m.*	52° 58′ 25″	63° 0′ 20″	66° 53′ 24″
20 December / 30 December	$7^h\ 0^m\ 0^s$ *v.* / $6^h\ 10^m\ 30^s$ *v.*	56° 34′ 16″	63° 6′ 1″	66° 54′ 29″
20 December / 31 December	$7^h\ 0^m\ 0^s$ *v.* / $4^h\ 15^m\ 16^s$ *m.*	57° 12′ 0″	63° 21′ 9″	66° 57′ 24″
20 December / 1 January	$7^h\ 0^m\ 0^s$ *v.* / $2^h\ 52^m\ 49^s$ *m.*	58° 57′ 1″	63° 23′ 0″	66° 57′ 45″
20 December / 2 January	$7^h\ 0^m\ 0^s$ *v.* / $6^h\ 27^m\ 30^s$ *v.*	60° 27′ 30″	63° 25′ 50″	66° 58′ 24″
20 December / 3 January	$7^h\ 0^m\ 0^s$ *v.* / $6^h\ 47^m\ 30^s$ *v.*	62° 18′ 39″	63° 47′ 58″	67° 2′ 32″
20 December / 4 January	$7^h\ 0^m\ 0^s$ *v.* / $2^h\ 3^m\ 24^s$ *m.*	62° 52′ 53″	63° 30′ 57″	66° 59′ 17″

215

Table of the comet's hourly motion.

[215] one framed table, divided by a double rule into the two groups given here, each with its side-note in the left margin beside its first rows. Each row gives two days on two lines, the earlier above the later, with the three values once for the pair. The value columns are headed "Gr.Min.Sec." and the time column "Hor.Min.Sec."; the angle column is headed "Angul. Orbit.& Æquatoris."

	Hour	20 December	21 December	22 December	23 December	24 December	25 December	26 December	27 December	28 December	29 December

[216] one framed table, divided by a double rule into the two halves given here, each with its own head row. Each day column is headed "Die N" over "Dec.Cur." or "Jan.Cur." (of the current December or January) and over the units of its two figures: "Gr.Min." (degrees, minutes) in the first sixteen columns, "Mi. Sec." (minutes, seconds) in the last four, 5 to 8 January. "Horâ" (at the hour) heads the hour column. The labels for hours before noon (printed in the pieces "Ho", "ræ ante", "meridia", "næ."; "ræ ante-" in the lower half) and for hours after noon ("Ho", "ræ poſt-", "meridia", "næ.") are set sideways in a narrow column at the left, each beside its run of twelve hours. The column for 20 December is blank from 12 before noon to 6 after noon. Rules divide the rows into groups of three.

	Hour	20 December	21 December	22 December	23 December	24 December	25 December	26 December	27 December	28 December	29 December
Hours after noon	12		8° 16′	18° 38′	27° 2′	34° 1′	39° 48′	44° 37′	48° 31′	51° 40′	54° 4′

217

Now that the comet's proper motion has been properly determined in this way, it follows that we should examine with equal care the angle between the orbit and the ecliptic. As we said above, this angle was not of quite the same size throughout the whole time the comet shone, as the table inserted on page 106 shows. At the start, on 23 December, it was 73° 59′; it then decreased gradually up to the 27th; from that day it increased again, though not altogether evenly, but more and more from day to day, while still keeping a certain fixed proportion, up to 7 January, when it was found at its greatest of all, namely 75° and 3′.

[Margin: Quâ ratione Angulus Orbitæ & Eclipticæ variatus fuerit?] *In what way the angle between the orbit and the ecliptic varied.*

Very nearly the same kind of motion appeared about the point of intersection of the comet's orbit and the ecliptic, that is, the comet's northern node [Nodum Boreum]. From the beginning up to 27 December it moved with a retrograde motion, though a scarcely perceptible one; after that it took on a direct motion, and one that grew gradually faster. Considering the matter somewhat more exactly, and examining all the calculations of this angle and of the node carefully, we noticed that on 23 December the node lay in ♉ 28° 33′; on the 26th and 27th in ♉ 28° 31′, where it stayed as if at a station; but on 7 January in ♉ 29° 7′. So the difference of this variation, counted from that station, came to 36 minutes.

[Margin: De motu hujus Cometæ Nodi Borei.] *On the motion of this comet's northern node.*

Likewise the angle was at its smallest of all around 26 and 27 December, namely 73° 57′, and at its greatest of all around the comet's disappearance, so that the difference of this angle grew to 1° 6′. This is clearer from the attached table, in which we have chosen to set out the variation for every day, both of the angle and of the place of intersection.

[Margin: Quanta variatio anguli Eclipticæ & Orbitæ extiterit.] *How great the variation of the angle between the ecliptic and the orbit was.*

Table showing the variation of the angle between the comet's orbit and the ecliptic, and also the motion of its northern node, for each single day.

[217] one framed table, divided by a double rule into the two halves given here, each with its own head row, laid out as the table of hourly motion on the facing page. Each day column is headed "Die N" over "Dec.Cur." or "Jan.Cur." and over "Gr.Min." (degrees, minutes) or a variant of it; "Horâ" heads the hour column; the labels for hours before and after noon stand sideways at the left, split by the rules into the same pieces as on p. 153. The column for 20 December is blank from 12 before noon to 6 after noon. Rules divide the rows into groups of three. The fractions are set as a small numerator above a small denominator.

218

Although I do not think anyone can still doubt the certainty of this motion, especially if one weighs carefully with how much diligence, and from how many and how varied examples, we derived it, computing it not only from the observed distances of the comet from the fixed stars but also, with by far the

[218]a framed table set at the left of the text, which runs on beside it. The date column is headed "Menſ. Dies" over "Ann.1652." (month, day; year 1652), and "A.1653" (year 1653) stands in it beside 2 January. The angle column is headed "Angul.Orb. Com. & Ecl." over "Grad. Min.", the node column "Nodus Bor." over "Gr. Min. S." (degrees, minutes, sign); each difference column is headed "differ" alone, with no unit. Each pair of difference figures is printed on a half-line between the two dated rows it separates, and is given here on a row of its own in the same place. Rules divide the dated rows into groups of three, 7 January standing alone below the last rule.

greatest diligence, from the comet's altitudes and azimuths, let us nevertheless, for the sake of a fuller investigation, see whether the angle between the comet's orbit and the equator, together with its node, also underwent some change or anomaly. If it grew in the same way as the angle between the orbit and the ecliptic (keeping, however, the due proportion with respect to the inclination of the equator to the ecliptic), that is a further sure sign that everything truly stands as we said above about the angle of inclination to the ecliptic.

[Margin: Et angulus Orbitæ & Æquatoris nec non Nodus var.ationi fuit obnoxius.] *The angle between the orbit and the equator, and the node too, were also subject to variation.*

Having therefore carefully weighed the angle of intersection with the equator and its node, derived in Section IX and set out on page 108, we found that near the start of the appari- tion the angle of inclination to the equator was slightly diminished, but from the 27th or 28th was gradually increased again. The same thing happened likewise with its node. At first it was carried toward the preceding signs [in antecedentia], but with a scarcely perceptible motion; then, after making a station, it became direct, though advancing at the slowest pace, as the attached small table sets out. In it we have chosen to record, for each single day of the whole apparition, both the decrease and the increase of the angle, and also the anomaly of the node, as exactly as was possible.

From the table it is plain that on 26 December this angle was 63° 0′ 44″; that around the station it did become smaller by a few minutes; but that afterwards it grew again, up to the comet's extinction, at which time it was found to be about 64° and 18′. The difference in the variation of the angle was therefore 1° 18′, whereas the difference of this node scarcely grew to 15′.

[Margin: Magnitudo anguli, ejusq́; variatio.] *The size of the angle, and its variation.*

Table showing the variation of the angle between the comet's orbit and the equator, and also the motion of its northern node, for each single day.

Year 1652; month, day	Angle of the comet's orbit and the equator (degrees, minutes, seconds)	Difference (minutes)	Northern node (degrees, minutes, seconds)	Difference (minutes)

219

To anyone asking why the node of the comet's orbit and the equator did not acquire quite the same difference as the node of the comet's orbit and the ecliptic, namely 36 minutes, the answer is this: since the comet's orbit cut the equator more obliquely, because of its greater obliquity with respect to the ecliptic, the motion of the point of intersection with the equator was necessarily slower as well, and so it could not follow a similar pattern of variation.

We have therefore sufficiently demonstrated that these angles, and likewise the places of the nodes, changed in a certain fixed way, even though I have no one to support me on this point. But why did none of all the other observers notice this as well? I will tell you. First, some of them no doubt imagined that no motion could occur in this angle, especially if, as many believe, they move in a great circle; and, led by this preconceived opinion, they settled on that angle as derived from only one or two examples. Others, lacking many suitable observations, could detect scarcely any perceptible change. For you should know that very many and very certain observations are needed to investigate such extremely subtle matters; with observations obtained in the common way, for instance by stretched threads, or with cruder instruments, these things can by no means be investigated. And since very few have drawn such observations from the sky, it was not granted to them to perceive the motion of the angle so often mentioned, and of the node.

[219] a framed table set at the right of the text, which runs on beside it. The date column is headed "Ann.1652." over "Menſ. Dies" (year 1652; month, day). The angle column is headed "Angul. Orb." over "Com. & Æq." over "Gr.Min.Sec.", the node column "Nodus Bor." over "Gr. Min.Sec."; each difference column is headed "differ" over "Min." (minutes). Each pair of difference figures is printed on a half-line between the two dated rows it separates, and is given here on a row of its own in the same place; none stands between 26, 27, 28 and 29 December. Rules divide the dated rows into groups of three, 7 January standing alone below the last rule.

[Margin: Cur nemo omnium, præter autorem, motum anguli Eclipticæ & Orbitæ, nec non Nodi animadverterit?] *Why no one but the author noticed the motion of the angle between the ecliptic and the orbit, and of the node.*

Furthermore, this occasion raises a question, and not without reason: whether phenomena of this kind also occurred, and were detected, in all the remaining comets, or only in some. Since this question has not yet, as far as I know, occurred to astronomers [Aſtroſophis], it deserves, believe me, to be fully

[Margin: An omnes & ſinguli Cometæ ſimilem referant motum?] *Whether each and every comet shows a similar motion.*

investigated: and this I now gladly set about doing. To begin with, however, I shall first lay my own view of the matter before you. To tell the truth, I am fully resolved that this variation of the angle of inclination of the orbit, and of the point of intersection, has always been common to all comets, though with an entirely different manner of motion, as we shall explain at greater length below.

It may indeed be objected that astronomers by no means the least — that noble investigator of the heavens and the stars, Tycho Brahe, for the comets of 1577 and 1590; Willebrordum Snellium [Willebrord Snel] and Peter Crüger for the comet of 1618; and, not to mention others, most distinguished men — found and established exactly the opposite. Just as these men were by far the most practised in observing and investigating celestial things, and the most ingenious, so that scarcely anyone can be ranked equal with them in this business, let alone above them — above all Tycho, whose supreme diligence in measuring the phenomena of the heavens, and whose keenness and penetration of intellect and judgement, the whole learned world rightly looks up to and celebrates — so I myself judge this objection to be weighty indeed. We shall therefore do rightly, and very well, if we inquire somewhat more carefully into their opinion.

[Margin: Quinam inter Autores circa Cometas fixum angulum Orbitæ, & Nodum ſtatuerint?] *Which of the authors held that the angle of the orbit, and the node, are fixed in comets.*

First, as regards Tycho, I very readily grant that in Chapter V, on the comet of 1577, he showed from seven different and duly computed examples that the angle of inclination to the ecliptic was of the same size, namely 29° 15′, and that the point of intersection lay, through all the days the comet shone, in ♐ 20° 55′, as is clear from this small table. The first column contains the observations of those days from which Tycho himself derived the angle and the node; the second, the longitudes; the third, the comet's latitudes; and the fourth and fifth, the angle and the node.

[Margin: Tycho, diverſis exemplis in Cometâ an. 1577. oſtendit angulum inclinationis invariabilem extitisſe.] *Tycho showed by various examples, in the comet of 1577, that the angle of inclination was invariable.*

Angle of inclination to the ecliptic, and the node, of the comet of 1577, according to Tycho's calculation.

Year 1577; month, day	Longitude of the comet	Latitude of the comet	Angle of inclination	Node
November 23	3° 31′ ♒	20° 45′ *B*		
			29° 13′	20° 52′ ♐

220

Moreover, in Chapter VI, where he examines the said angle in turn, he insists again and again that this comet, by its proper motion, described a circle in the sphe- re that was exactly a great circle, held midway between its own poles, and that in the whole time it lasted it never deviated from that circle to one side or the other. Above all, on page 103, he concludes in these words: *It is therefore plain and sufficiently proven — the very thing we asserted from the beginning — first, that the comet by its motion described an exactly great circle, dividing the sphere into two equal halves; for everywhere the angle of inclination of the comet's circle to the ecliptic remained of the same size, namely 29° 15′. That it sometimes varied by two*

[220] a framed, ruled table in the body's measure. The date column is headed "Anno 1577" over "Menſ. Dies" (year 1577; month, day); the longitude column "Long. Com." over "Gr.Min. S." (degrees, minutes, sign); the latitude column "Latit. Com." over "Grad.Min."; the angle column "Angulus inclin." over "Grad. Min."; the node column "Nodus." over "Grad. Min. S.". The table is ruled into seven groups, each of two dated rows, a November date over a December or January date; the angle and node of each group are printed once, centred on the half-line between its two dated rows, and are given here on a row of their own in the same place. The page sets "B" after every latitude, unexpanded. On 2 January the page sets the Sagittarius sign after the longitude 10° 54′, where every other December and January row carries the Pisces sign.

or three, or at most five minutes (which nevertheless rarely happened), will easily be excused by those who understand, and will be counted as nothing. Therefore, since the inclination of the comet's path to the ecliptic is found to be the same everywhere throughout the whole time of its apparition, those in doubt will not be hard to persuade — provided they understand the principle of the circles of the sphere — that the arc the comet described by its motion is a portion of a great circle in the sphere, no less than the ecliptic, toward which it everywhere kept the size of the same angle; and that it had its own poles and stood equally distant from them, as the ecliptic does from its own; in the same way as the equator and the ecliptic stand in a mutual relation with respect to their poles, and although they intersect each other, each nevertheless, by reason of its own pole, describes a great circle in the sphere.

[Margin: Cometa anni 1577 in circulo incesſit maximo.] *The comet of 1577 moved in a great circle.*

And so it is perfectly true that Tycho firmly believed the angle of inclination was always equal, and that the node stayed fixed at the same point of the ecliptic. But I, with all respect to the honour of that great man, think quite otherwise: namely, that the said angle increased gradually from the beginning of the apparition up to its end, and likewise that the node advanced in the order of the signs, though very slowly, as I shall shortly demonstrate clearly by solid arguments. You are not, however, to suppose that I wish to call either Tycho's observations or his calculations into question — far be it, far be it indeed! For I know very well that in this study, and especially in cometography [Cometographico], he had scarcely anyone his equal; and indeed that more diligent and more certain observations, and more accurate calculations, can hardly ever be had. All we find wanting is this: that he did not seek this angle in order, as it ought to have been done, and as we advised above. For he set up the computation of this same angle of inclination only for some intermediate days, namely from 30 December to 12 January, whereas he ought to have investigated it for all the days of its shining, the first as well as the last, that is, from the middle of November up to the end of January; and to have done so in such a way that in every calculation he bound the observations of all the remaining days to one observation made near the beginning of the comet's apparition and more certain than the rest — as we did above with our own comet.

[Margin: Autor contra opinionem Tychonis ſtatuit angulum inclinationis Cometæ iſtius continuò crevisſe.] *Against Tycho's opinion, the author holds that this comet's angle of inclination increased continually.*

[Margin: Judicium Autoris de Tychonis obſervationibus.] *The author's judgement of Tycho's observations.*

Therefore, so that we may get to the bottom of this business more successfully, I have chosen to examine afresh, by our own method and without regard to the trouble of the labour, the said angle between the orbit and the ecliptic, and also the node, of the comet of 1577, keeping as a standard in every investigation the first observation, made by Tycho on 13 November. But so as

not to burden you with laborious calculation, let us set out only the givens and the results, at a single glance, in a small table.

[Margin: Angulus orbitæ & Eclipticæ ab Autore denuò inveſtigatus.] *The angle between the orbit and the ecliptic investigated afresh by the author.*

Angle of inclination to the ecliptic, and the node, of the comet of 1577, according to Hevelius's calculation.

Year 1577; month, day	Longitude of the comet	Latitude of the comet	Angle of inclination	Node
November 13	7° 15′ ♍	8° 59′ *B*		
			29° 10′	20° 48′ ♐
November 20	26° 59′ ♍	18° 15′ *B*		
November 13	7° 15′ ♍	8° 59′ *B*		
			29° 11′	20° 48′ ♐
November 23	3° 31′ ♒	20° 45′ *B*		
November 13	7° 15′ ♍	8° 59′ *B*		
			29° 11′	20° 48′ ♐
December 10	25° 47′ ♒	26° 50′ *B*		
November 13	7° 15′ ♍	8° 59′ *B*		
			29° 11′	20° 49′ ♐
December 17	1° 17′ ♓	27° 46′ *B*		
November 13	7° 15′ ♍	8° 59′ *B*		
			29° 13′	20° 50′ ♐
December 30	9° 14′ ♓	28° 42′ *B*		
November 13	7° 15′ ♍	8° 59′ *B*		
			29° 13′	20° 50′ ♐
January 9	14° 15′ ♓	29° 3′ *B*		
November 13	7° 15′ ♍	8° 59′ *B*		
			29° 16′	20° 52′ ♐
January 16	18° 8′ ♓	29° 14′ *B*		
November 13	7° 15′ ♍	8° 59′ *B*		
			29° 19′	20° 54′ ♐
January 26	20° 15′ ♓	29° 18′ *B*		

221

So you see that the angle of inclination to the ecliptic was only 29° 10′ on 20 November, but that it then increased gradually up to 26 January, at which time it was 29° 19′, so that the difference over the whole duration was 9 minutes. Tycho, however, since he computed the said angle only for the end of December and about the beginning of January, that is, for the intermediate

[221] a framed, ruled table at the head of the page, headed as the table on p. 157: "Anno 1577" over "Menſ. Dies"; "Long. Com." over "Gr.Min. S."; "Latit. Com." over "Grad.Min."; "Angulus inclin." over "Grad. Min."; "Nodus." over "Grad. Min. S.". It is ruled into eight groups, each pairing the observation of 13 November with one later observation; the angle and node of each group are printed once, centred on the half-line between its two dated rows, and are given here on a row of their own in the same place. The page sets "B" after every latitude, unexpanded.

time, found it to be 29° 13′; and that is indeed the size it truly had, as my own calculation also attests. But near the beginning, around 20 December, it was certainly smaller, and toward the end, in turn, somewhat larger. The same held for the node of this comet. On 20 November it stood at 20° 48′ of Sagittarius; but then from day to day it moved on in the order of the signs, so that on 26 January it was found at ♐ 20° 54′. Tycho, by contrast, fixed that point of intersection as immovable at ♐ 20° 55′, which certainly ought in no way to have been done, since not even near the end of the apparition had it quite got that far. Indeed, not even his own calculation shows this; rather, if the greater part of the investigations is to decide, the node lay about the beginning of January at 20° 51′, and my calculation also agrees with this.

[Margin: Demonſtratur dictum angulum & Nodum variatos eſſe.] *It is demonstrated that the said angle and the node varied.*

You may indeed retort that Tycho nevertheless, in Chapter VI, page 97, where he brings the angle between the orbit and the ecliptic back to the anvil for each single day, established the said angle firmly at 29° 15′. But the answer is that scarcely a very few examples of the calculation there agree with one another at all: he finds the angle now 5 minutes smaller, now as many minutes larger, as is plain from Tycho's own calculation, which I have set out in this small table.

[Margin: Vnde Tycho in contrariam devenerit ſententiam.] *What led Tycho to the contrary opinion.*

According to Tycho.

Year 1577; month	Day	Angle between orbit and ecliptic
November	13	29° 20′
	14	29° 12′
	15	29° 14′
November	20	29° 15′
	21	29° 14′
	23	29° 14′
November	25	29° 15′
	29	29° 12′
	30	29° 20′
December	1	29° 15½′
	10	29° 12′
	12	29° 13′
December	13	29° 14′
	14	29° 14½′
	17	29° 13′
December	23	29° 18′
	30	29° 12′
	31	29° 12′
January	1	29° 14′
	2	29° 13½′
	5	29° 13′

Year 1577; month	Day	Angle between orbit and ecliptic
January	9	29° 13′
	12	29° 16′
	26	29° 18′

222

This faltering of the calculation, however, is certainly not to be attributed to some unsteady observations, as Tycho indeed persuades himself. Rather, it plainly arose from the fact that in all the examples he always used the same first place of intersection, and one advanced too far in the order of the signs [in conſequentia], whereas he ought to have used a different one for each single day, by reason of the variation. Therefore, if at the beginning, namely on 13 November, he had assumed the node not at 20° 55′ but at ♐ 20° 48′, where it truly was at that time, then surely the angle of intersection with the ecliptic would not have come out as large as 29° 20′, but barely 29° 10′. Accordingly, since he erred on this point in every calculation, that examination is rightly rejected. But if one has a mind to examine the angle by this method, it is necessary, as we have often said, to presuppose the place of intersection corresponding to each single day; otherwise, surely, nothing certain is derived from it.

Tycho, however, is not to be reproached for having failed altogether to notice the anomaly of this angle. For since none of his predecessors had detected this inequality, let alone established it, he naturally presumed nothing of the kind, and so was easily deceived in this matter. There is, besides, the further point that the motion of this angle and of the node was very slow in that comet of 1577; and in such a case one errs far more readily than if the motion is fast. I do not doubt, therefore, that everyone will agree with me that the angle of inclination of the comet of 1577 increased continuously, and that its node advanced in the order of the signs, which is what we wished to show.

[Margin: Tycho excuſandus.] *Tycho is to be excused.*

But, you will say, granted that this really happened with the comet of the year 1577; yet Tycho, in a letter written to the most illustrious Prince of Hesse, on page 176 of his *Epistles*, indicates in clear words that matters stood quite otherwise with the comet of 1590, when he says: *Having compared with one another and carefully weighed the observations I obtained in the meantime, I find that this comet by its proper motion traced exactly the arc of a great circle, so that it deviated from it not at all, to this side or beyond, in the whole time it lasted. And this on the terms that, if that arc met the equator at 339° 45′ of it, it crossed it with an*

222 a small framed, ruled table, its caption "Juxta Tychonem." and head rows "Anno 1577" over "Menſis Dies", and "Angulus orb. / & Eclipt." over "Grad. Min.". The page prints it in two blocks side by side: the first, with caption and head, holds 13 November to 12 December; the second, without caption or head, holds 13 December to 26 January; they are given here as one table in the printed order. Each block is ruled into groups of three days, the month set once on the first row of each group.

inclination to it of 42° 0′, which was always alike, and remained entirely the same, etc. So he writes. From this it becomes plain that the angle of inclination and the node were stable; for whatever he states of the equator must also be understood of the ecliptic. Nevertheless I still hesitate over whether he examined everything properly himself: perhaps he was misled by one or another example of calculation obtained in a confused order. Therefore, since he did not add there the calculation itself of this angle and of the place of intersection, nor indicate from which observations those results were derived, I wished, for the sake of truth, to investigate it myself with due diligence, from the comet's given longitudes and latitudes for certain days. And so I found that the angle between the comet's orbit and the ecliptic was 21° 24′ on 26 February; that from that day it became gradually narrower up to 3 March, at which time it made a station [ſtationem fuisſe celebratam]; and that thereafter it became wider and wider again. The same happened with the node. At the beginning it stood at ♒ 21° 17′, yet it was carried with a very slow retrograde motion until 3 or 4 March, and afterwards became direct once more: just as

[Margin: Ex mente Tychonis Angulus inclinationis in Cometâ anni 1590 fuit ſtabilis.] *In Tycho's view the angle of inclination in the comet of 1590 was stable.*

[Margin: Autor demonſtrat Angulum inclinationis, Nodumq́; Cometæ 1590 variabilem extitisſe.] *The author demonstrates that the angle of inclination and the node of the comet of 1590 were variable.*

is plain from the accompanying small table, especially from the second, which shows for every day on which the comet shone the true daily motion both of the angle between the orbit and the ecliptic and of the place of intersection.

Angle of inclination to the ecliptic, and the node, of the comet of 1590, according to Hevelius's calculation.

Year 1590; month, day	Longi-tude	Latitude	Angle of orbit and ecliptic	Point of intersection
February 23	18° 27′ ♈	18° 14′ *B*		
			21° 24′	21° 17′ ♒

5	21° 14′	20° 30′
6	21° 16′	20° 37′

224

It is therefore sufficiently proven, from what has just been adduced, that in the comet of 1590 as well the angle of inclination was variable and the node movable.

Moreover, the most learned Willebrordus Snellius [Willebrord Snel], in his description of the comet, page 15, holds that the great and splendid comet of the year 1618 always described a great circle; which is plainly the same as if he had said that its angle of inclination was always of the same size. Peter Crüger too, a man of rare learning, agrees with him, in his *Uranodromus cometicus*, Chapter V, page 29, in these words: *Since, then, the calculation of this chapter testifies more than enough that the line, or arc of a circle, passing through the places of the comet on 8 and 29 December, likewise on 9 and 29, and on 8 and 15, always cut the equinoctial and the ecliptic in one and the same degree, it necessarily follows that all the places of the comet stood in one and the same great circle of the heavens; so that the comet's motion was in no way wandering and irregular, but that throughout the whole time it lasted it kept up the constant, regular motion of a circle, after the manner of the celestial bodies.*

[Margin: Quid Snellius & Crügerus de angulo inclinationis Cometæ 1618 ſenſerint.] *What Snel and Crüger thought about the angle of inclination of the comet of 1618.*

---

223 the left-hand of two framed, ruled tables set side by side. Its head: "Anno 1590" over "Menſ. Dies"; "Longitudo." over "Gr.Mi. S."; "Latitudo." over "Gr.Min."; "Ang.orb. & Eclip." over "Gr Min."; "Punct.inter- ſectionis." over "Gr.Mi. S.". It is ruled into four groups, each pairing the observation of 23 February with one later observation; the angle and node of each group are printed once, centred on the half-line between its two dated rows, and are given here on a row of their own in the same place. The page sets "B" after every latitude, unexpanded.

224 the right-hand table, framed and ruled. Its head: "Anno 1590" over "Menſ. Dies"; "Ang.orb. & Eclip." over "Gr.Min"; "Punct inter- ſectionis" over "Gr.Min. S.". It is ruled into three groups of three days; the month and the sign of Aquarius are printed only on the first row of each group, the other rows carrying the day and the figures alone.

I reply, however, that on that very same page Crüger himself freely admits that the angle between the comet's orbit and the ecliptic does not agree entirely from one calculation to another, saying: *The second investigation, although the whole calculation of the longitude and latitude, and of what follows from them, was repeated twice, deviates from the rest by half a degree; yet in such a way that this deviation causes little hindrance in this matter, as is known to those skilled in these things.* He seems, therefore, to have ascribed the variation of this angle to the observations, not to an inequality. I, however, am firmly convinced that something calling for deeper inquiry lies hidden there; above all since the most sagacious Kepler holds the plain opposite about this comet in several places in his History. First, on page 72, in the small table placed there: *But through the remaining half of December and at the beginning of January the latitudes coincide exactly; but from 4 January up to the end of its duration there again appears a most manifest and quite notable deflection from the path of the great circle toward the south.* Second, on page 97, Question V: *Why do they for the most part seem to describe great circles? Answer: It is not absolutely tr-*

[Margin: Crügerus inæqualitatem hujus anguli animadvertens, eam obſervationibus adſcribit.] *Crüger, noticing the inequality of this angle, ascribes it to the observations.*

[Margin: Kepplerus, planè contrarius eſt Crügero] *Kepler is plainly contrary to Crüger.*

ue, as appeared in the comet of 1618, whose path was winding; but its path appears a great circle insofar as the motion of the earth, by reason either of its speed or of its position, is not perceived in them. Third, he adds in Question VI: *Comets, once they have become slow, begin to curve their paths, as the comets of the years 1607 and 1618 did, and many others.*

[Margin: Cometa anni 1618 circa finem inflexit iter à circuli ſui tramite.] *Toward the end, the comet of 1618 bent its path away from the path of its circle.*

Severinus Longomontanus likewise asserts of the same comet, in the Appendix to the *Astronomia Danica*, page 35, that the comet departed, that is, a very little from the path of its circle. In the same way J. Bapt. Cysatus [Johann Baptist Cysat], too, in his *Mathemat. Astron.*, page 21, Porism 5: *Although* (he says) *the comet, from the beginning of December up to 5 January, when it had its greatest latitude, or up to 3 January, when it was a quadrant of its circle away from the section with the ecliptic, described a great circle fairly exactly, with the same angle of intersection with the ecliptic, as was shown in Problem 5 and Porism 1, yet after 7 January it seems to have bent away somewhat from this exact path toward the south.* Likewise on the same page, near the end: *Therefore the exact course through these two positions did not reach as far as the comet, but tended further toward the north by perhaps one degree or more; and so the comet was bending away toward the south from its straight path.* Finally, other very learned men have also noticed this very thing, as can be seen from Book III of the *Meteorologica* of Libertus Fromondus [Libert Froidmont], page 219: *I would have finished* (he says) *had this clause too not come to mind: why does the proper motion of certain comets twist itself at the end*

like a snail's shell, and bend away for a little from the segment of a great circle? For Cysat noted this, and so did our Godefridus Wendelinus [Govaert Wendelen], a man most worthy of a greater fortune, in the comet of the year 1618.

[Margin: Idem teſtatur Longomontanus.] *Longomontanus attests the same.*

[Margin: J. Bapt.Cyſatus.] *Johann Baptist Cysat.*

[Margin: Libertus Fromondus.] *Libert Froidmont.*

From this it is indeed clear that Kepler, Longomontanus, Cysat and Wendelen differ in this matter from Snel and Crüger by the whole heaven; but however that may be, I scarcely think that everyone will be satisfied by this argument drawn from authority. Therefore we ourselves computed in order, with the greatest care, this angle of intersection with the ecliptic, and its node, from Crüger's observations. We found that on 9 December the said angle was 64° 43′, but that with the passage of time it decreased continuously, so that on 29 December it was found to be only 63° 19′. The same happened with the place of intersection: from 9 December to the 29th of that month it advanced with a continuous motion in the order of the signs. But so that the decrease of the motion can be more easily understood and seen with the eyes, I have constructed two small tables of it, the second of which shows the anomaly both of the angle and of the node for every single day of the whole duration.

[Margin: Autorum diſſenſio.] *Disagreement of the authors.*

[Margin: Autor commonſtrat & hujus Cometæ 1618 angulum inclinationis, Nodumq́; variationi obnoxium fuiſſe.] *The author shows that in this comet of 1618 too the angle of inclination and the node were subject to variation.*

The observation made on 8 December does seem to waver somewhat; but this is to be ascribed to nothing other than that doubtful observation. For if the whole matter is weighed on an accurate balance, we find that a like motion truly occurred both in the angle of intersection and in the node.

From these well-founded demonstrations it is now sufficiently proven (Tycho, Snel and Crüger notwithstanding) that in those three comets, namely of the years 1577, 1590 and 1618, the angle of inclination was always varying and the node movable.

Angle of inclination to the ecliptic, and the node, of the comet of 1618, from Crüger's observations and Hevelius's calculation.

Year 1618; month, day	Longitude	Latitude	Angle of orbit and ecliptic	Node

226

But so that the matter may be clearer still, I would have you know that Christophorus Rothmannus [Christoph Rothmann], a man otherwise of singular learning, likewise noticed with complete certainty in the comet of the year 1585 that the same angle of intersection decreased from the comet's first rising

[225] the left-hand of two framed, ruled tables set side by side at the head of the page. Its head: "Anno 1618" over "Menſ. Dies"; "Longitudo." over "Gr.Mi.Sec. S."; "Latitudo." over "Gr.Min.Sec."; "Ang.orb. & Eclip." over "Gr.Min."; "Nodus." over "Gr.Mi. S.". It is ruled into four groups, each pairing the observation of 8 December with one later observation; the angle and node of each group are printed once, centred on the half-line between its two dated rows, and are given here on a row of their own in the same place. The page sets "B" after every latitude, unexpanded. In the 20 December row a raised point stands between the seconds and the sign.

[226] the right-hand table, framed and ruled. Its head: "Anno 1618" over "Menſ. Dies"; "Ang orb. & Eclip." over "Gr.Min."; "Nodus" over "Gr.Min. S.". It is ruled into seven groups of three days; the month and the sign of Scorpio are printed only on the first row of each group, the other rows carrying the day and the figures alone.

up to its extinction. For he says in Chapter II, page 85, of his description of the comet: *It is therefore manifest that the angle of intersection of the comet's circle and the ecliptic decreased, by 26 minutes in the first interval, but by 1 degree in the other.* Tycho himself also attests the same about the same heavenly body, in Book I of his *Epistolae Astronomicae*, page 15, in these words: *But if this motion is weighed geometrically by means of triangles, it will appear that by its own proper course it described an arc of a circle that was truly a great circle, which nevertheless admitted, successively, a somewhat variable inclination to the equator and the ecliptic, and which crossed the equator at 14° 55′ from the vernal intersection, and the ecliptic at ♈ 27° 38′. The change (of which I spoke) went by this law: around the midnight following the noon of the 18th, the angle of declination to the equator was about 45½ degrees, and to the ecliptic 27° 17′, and it diminished step by step, so that on 14 November it was 44° 50′ to the equator. The inclination to the ecliptic was 22° 21′; and at the end of the apparition, on the 12th, the same was found to be 44° 19′ with respect to the equator, but 21° 34′ with respect to the ecliptic. And in this way, in the intermediate spaces too, the obliquity of the portion of the comet's circle to the equator and the ecliptic decreased little by little, by a regular diminution.* This is evident more clearly still from his own small table on page 19 of the *Epistolae*. And so the variation of the angle to the equator grew to 1° 18′, and that to the ecliptic to 1° 52′, over the whole time of the apparition. Likewise the motion of the comet's orbit and the ecliptic also advanced in the order of the signs [in consequentia], though very slowly: over the whole time of its duration, scarcely about 20 minutes. I have been glad to add here as well its motion and its place in the ecliptic, worked out by my own effort. It was investigated by the method we use elsewhere, taking as the foundation, namely, the observation made by Tycho on 19 October, when the comet stood at 21° 45′ of longitude and 2° 30′ of southern latitude.

[Margin: Rothmannus idem inCometâ 1585 deprehendit.] *Rothmann found the same in the comet of 1585.*

[Margin: Etiam ab ipſo Tychone motus inclinationis orbitæ inCometâ anni 1585 animadverſus eſt.] *Tycho himself, too, noticed the motion of the inclination of the orbit in the comet of 1585.*

[Margin: Motus orbitæ & Eclipticæ Cometæ anni 1585 directus fuit.] *The motion of the orbit and the ecliptic of the comet of 1585 was direct.*

Table of the motion of the inclination of the comet's orbit, to the equator as well as to the ecliptic, and of the point of intersection with the ecliptic, for the comet of 1585.

Year 1585; month, day	Inclination to the equator, from Tycho's work	Inclination to the ecliptic, from Tycho's work	Northern node of the comet, from Hevelius's work

And so this too is very true: that the angle of inclination of this comet was likewise subject to change, but to a supremely regular one.

Lastly, in the comet of the year 1607, as Kepler attests in his History of Comets, page 97, the angle so often mentioned changed in roughly the same way. Longomontanus too agrees with this, on page 29 of *De novis Cœli phænomenis*, when he says: *But it is to be noted that the said comet crossed the equator on 29 September, a little after 236 degrees; and indeed it was detected to have first evidently deviated from the path of a great circle on 1 October, when it had almost reached the stars in the left hand of Ophiuchus.* Hence, therefore, I think it sufficiently clear that the matter was not otherwise, although I could not examine these things myself by calculation, for lack of sufficient observations.

227a framed, ruled table. Its head: "Anno 1585" over "Menſ. Dies"; "Inclinat. ad Æqu. operâ Tychonis." over "Grad. Min."; "Inclinat. ad Eclipt.operâ Tychonis." over "Grad. Min."; "NodusCom. Bor. operâ Hevelii." over "Gr.Min. S.". It is ruled into ten groups, nine of three days and the last of two; the month is printed on the first row of each group and again where November begins inside a group, the last two groups setting "Nov."; the sign of Aries is printed only on the first row of each group. The node column passes from 27° 57′ on 13 November to 27° 59′ on 14 November, as printed.

[Margin: Idem motus etiam in Cometâ anni 1607 obſervatus eſt.] *The same motion was observed in the comet of 1607 as well.*

Yet before we leave this subject, let us try to confirm this matter by some observations of the older astronomers as well: namely by the three comets observed by that most diligent man Petrus Appianus [Peter Apian] in the years 1531, 1532 and 1533, and accurately described in his most ample *Mathematicum Cæsareum* [Mathematico Cæſareo]. Having therefore got through a laborious calculation, which it would be too tedious to add here, we have found more than enough that in all three both the angle of the comets' path and their node were driven by a definite motion, but in each comet by a peculiar and quite different one. In the earlier comet, that of the year 1531, the angle between the comet's path and the ecliptic was 23° 17′ around its first sighting, but it gradually increased up to its disappearance. Its node, however, was carried against the sequence of the signs, and indeed with a fairly swift motion, which we have scarcely noticed in other comets so far. In the one observed in 1532, by contrast, the inclination to the ecliptic increased at first; then, after a stationary period, it decreased in turn at the end, while the node meanwhile tended continuously in the order of the signs. But in the later comet, which shone in the year 1533, the said angle decreased throughout the whole time of its duration, while the node, like that of the preceding comet, likewise advanced according to the order of the signs; as is clearly seen from the accompanying small table. The first column, the month and the day on which

[Margin: Antiquiorum quibusdam exemplis idem probatur.] *The same is proved by some older examples.*

[Margin: Motus inclinationis Orbitæ & Nodorum Cometæ 1531.] *Motion of the inclination of the orbit and of the nodes of the comet of 1531.*

[Margin: Cometæ anni 1532.] *Of the comet of 1532.*

[Margin: Cometæ anni 1533.] *Of the comet of 1533.*

the comet was observed, the second the longitude, the third the latitude, the fourth the angle of the orbit and the ecliptic, the fifth the place of intersection with the ecliptic, while the sixth shows its own proper motion in the circle of its path.

Ephemeris of the three comets observed by Peter Apian, constructed by Johannes Hevelius.

Comet	Month, day	Longi-tude	Latitude	Angle of orbit and ecliptic	Place of intersection	Proper motion

228

And so, I think, this motion of the inclination of the orbit and of the node is established again and again, and sufficiently. For my part, to confirm the matter further, I had resolved to bring forward still more examples of comets, if suitable and accurate observations, of the kind that the elucidation of this matter uniquely demands, had been at hand. But among the older astronomers such observations are found not at all, and among the more recent scarcely a very few. The greatest part of the astronomers takes delight rather in vain and ambiguous predictions, and strives to please the common people, than to search thoroughly into such very subtle phenomena of the heavens. Yet it matters indeed not a little to all philosophers to know these things rightly: first, namely, whether such a phenomenon really occurs only in certain comets, or in all of them; second, what the genuine cause of this appearance is; and third, to say nothing of the rest, whether this phenomenon is a certain sign of some notable parallax. The most distinguished Johann Baptist Cysat agrees with me, on page 21 of his description of the comet of the year 1618: *The comet was deflected toward the south from its straight path. This bending would indeed be a phenomenon of great moment, if it were confirmed by more observations. We do not wish to decide from our one comet. It may be that the stars on the globe were not placed accurately enough, through the carelessness of the one who drew them on, or*

[228] a framed, ruled table. Its head: "Cometa."; "Menſ. Dies"; "Longitudo." over "Gr.Min. S."; "Latitudo." over "Gr. Min."; "Angulus or- bit.& Eclip." over "Grad. Min."; "Locus inter- ſectionis." over "Gr. Mi, S."; "Motus pro- prius." over "Grad. Min.". Double rules divide the three comets, and a single rule divides each comet's rows into two groups (1531: 14–16 and 17–23 August; 1532: 2–19 October and 31 October–8 November; 1533: 18–21 and 23–25 June). In each first group the last three columns are blank on the earlier rows, and a single value is printed on the group's last row, with a brace in the angle column joining that row to the rows above it. The page sets "S." or "A." after every latitude, unexpanded. The latitude for 23 August 1531 is printed 34° 31′, after 16° 32′ on 22 August.

that the observation of the comet's position in one straight line with two fixed stars (however accurately it is made) is not so infallible. We therefore leave this porism undecided. From this one can see that the same author already at that time had some inkling of the motion of the inclination of the cometary orbit; but since he had not yet become sufficiently certain of the matter, he was afraid, as is fitting, to lay down anything certain.

[Margin: Pleriq; Aſtronomorum vanis oblectantur prædictionibus.] *Most astronomers delight in vain predictions.*

We do not overstep the limits, however, if we declare and finally conclude, both from our own comet of the year 1652 and from all the others adduced above (whose observations were drawn from the most trustworthy writers and worked out by our own effort), that the angle of inclination of the comet's orbit, to the equator as well as to the ecliptic, and also the nodes of the comet, are variable and movable. I add that later generations will certainly notice that such a thing has happened not only in the comets mentioned but also in all subsequent ones, if any appear, provided that these phenomena are observed by them with larger and suitable instruments. We wish all mathematicians, each and every one, to be asked again and again to apply themselves diligently to this study in their own time.

Finally, it should be well noted here that this angle and the node vary neither in all comets nor at all times in one and the same way. For sometimes the angle of inclination widens from the beginning to the end in a certain proportion, and the node is carried against the order of the signs [in antecedentia], the longitude being direct and the latitude always northern: witness the comet of the year 1531, observed by Apian. Sometimes the angle itself narrows around the first appearance, becomes stationary around the middle, and widens again around the last, the node and the longitude being direct throughout, and only the latitude diverse [diversâ]; as appeared in the comet of the year 1532. Sometimes the angle decreases throughout, the node meanwhile tending in the direct sense, the longitude being retrograde and the latitude increasing: as was found in the comet of the year 1533. Sometimes, over the whole duration, the angle of inclination is compressed more and more, the node indeed being direct, but the longitude retrograde, and the latitude increasing toward the north. Sometimes the angle increases continually, the node meanwhile advancing step by step in the order of the signs, as is clear enough from the comet of the year 1577, whose longitude was always direct and whose latitude was increasing the whole time. Sometimes the angle of inclination decreases continually, the longitude being direct but the latitude diverse, as was observed in the comet of the year 1585. Sometimes this angle is found decreasing from the beginning of the apparition, stationary in the middle, and increasing again at the end, as the comet of the year 1590 clearly attests, although the motion of its longitude and latitude, over the whole time of its duration, agrees entirely with the preceding comet. Sometimes the angle of inclination increases throughout, the motion of the node being reciprocal, the longitude direct, and the latitude entirely diverse:

as is clearly evident from the comet of the year 1607. Sometimes the angle diminishes from around the comet's first rising up to its station, and afterwards increases again, the node being at first direct, then stationary, and lastly direct; while the longitude was continually retrograde, and the latitude increasing at the first appearance, then stationary, and finally decreasing: as happened with the comet of the year 1618. Sometimes the angle increases little by little over the whole time of the duration, the node meanwhile advancing according to the sequence of the signs, although the longitude is retrograde at the beginning and direct at the end, while the latitude is continually increasing: witness our own comet of the year 1652. But so that this variation in the comets mentioned above may be perceived still more clearly by everyone, I have been pleased to add the following small table. Its first column indicates in what

[Margin: Omnium Cometarum inclinatio orbitæ variabilis, & Nodi mobiles ſunt.] *The inclination of the orbit of all comets is variable, and their nodes are movable.*

year the comet was observed; the next divides the time of the apparition into beginning, middle and end; the third sets out the angle of inclination; the fourth, the node; the fifth, the longitude; the sixth, the latitude; and the last supplies the comet's motion in its own orbit at those different times.

Variation of the angle of inclination, of the node, of the longitudes, of the latitudes, and of the motion in the circle of its path, of nine comets.

Comet of the year	Time of the apparition	Angle of inclination	Node, or place of intersection	Longitude	Latitude	Motion of the comet in its path
1531	Around the beginning	Increasing	Retrograde	Direct	Decreasing *B.*	Fairly fast
	middle	Increasing	Retrograde	Direct	Decreasing *B.*	Faster
	end	Increasing	Retrograde	Direct	Decreasing *B.*	Slacker
1532	Around the beginning	Decreasing	Direct	Direct	Decreasing *A.*	Fairly slow

229

I therefore think it rightly said that the inclination of the angle, to the equator as well as to the ecliptic, and the node of the comets undergo their own variations and vicissitudes, yet bounded by the utmost and by a certain regularity, or rather by a regular inequality (which I would have you note well); so that each and every comet moves in an entirely peculiar way, after the manner of the planets, and very rarely does one correspond to another altogether in every respect. This is what we wished to demonstrate, as it were, to the eye.

[Margin: Cometæ more Planetarum, moventur, ratione anguli inclinationis &Nodorum.] *Comets move after the manner of the planets with respect to the angle of inclination and the nodes.*

Section XI. To Investigate the Time at Which a Comet Crossed the Equator and the Ecliptic [SECTIO XI. Tempus,quo Cometa Æquatorem,Eclipticamq́; trajecerit, indagare.]

Before we go in search of that very thing, let us resolve this question: whether, namely, each and every past comet has crossed the equator and the ecliptic, and whether future ones too must necessarily cross those circles. It should be known, then, to be brief, that since no comet has ever, as far as is clear from

229a framed, ruled table of seven columns. Its head: "Cometa / anni"; "Tempore appa- / ritionis."; "Angulus incli- / nationis."; "Nodus ſ.Locus / interſect."; "Longitudo."; "Latitudo."; "Motus Cometæ / in ſuo tramite.". Nine blocks of three rows, one for each comet, divided by rules; the year is printed once per block, and "Circa" once per block, before "Initium", with "Medium" and "Finem" alone on the rows below. The page sets "B." or "A." after every latitude word, unexpanded, and "Med." in the 1585 motion cell, unexpanded. The table prints no figures beyond the years.

their history, been entirely without all declination and latitude, but has been now northern, now southern, it is readily gathered that no comet has ever arisen that did not at a certain time intersect the said circles. This holds, however, on this express condition: unless the comet was extinguished by diminution, or wholly absorbed by the rays of the Sun, before it could reach that point by its proper motion in its own path. And finally, unless one of the comets travelled above or below the obliquity of the ecliptic, at 24 degrees and more, from west to east, that is, or conversely from east to west, namely in the northern or the southern part of the heavens, around the tropics.

Then, too, we can scarcely persuade ourselves that it could easily happen (although it is not altogether absurd either) that some comet should perpetually take the ecliptic or the equator as its path so strictly that it would not deviate in some way toward this region or that. Even supposing that some comet were found in future that adhered exactly to the ecliptic at all times, it could still in no way avoid the equator in the course of time. For just as the ecliptic intersects the equator at a certain angle, so such a comet will surely intersect that circle. The exception is those comets that are carried under the poles on a course roughly parallel to the equator or the ecliptic.

In the same way, if a comet travelled in the equator, it would in turn cross the ecliptic. Hence we conclude quite rightly that every comet tending from south to north, or from north to south, reaches either both great circles, or at least one of the two, provided that it remains visible long enough (which I would have you note well).

Meanwhile, however, you should know that very many comets have shone whose line of travel never cut either the equator or the ecliptic. This, as we said just now, arises from nothing other than that they did not remain in our sight long enough to reach those circles by their own proper motion. Of this kind was the comet observed by Apian in the year 1531: because it was carried above the ecliptic toward the north, from west to east, and in the more northern signs, over a space of only a few days, it is certainly established that it did not reach the equator and the ecliptic. To that number must also be counted the comet of the year 1533, noticed by the same observer: since it was of still shorter duration, and travelled both nearer the North Pole and from east toward west, it therefore touched the said circles all the less, let alone crossed them. To this also belongs the comet of the year 1590, accurately noted by Tycho,

[Margin: An omnes & ſinguliCometæ, ex certâ lege Æquatorem Eclipticamq́; trajiciant ?] *Whether each and every comet crosses the equator and the ecliptic by a fixed law?*

[Margin: Multi Cometarum necÆquatorem nec Eclipticam transgrediuntur.] *Many comets cross neither the equator nor the ecliptic.*

whose latitude and declination too were found to be northern over the whole time of its duration, and which therefore by no means reached the intersection of those circles. All the remaining comets, however, namely those of the nine

mentioned in the preceding Section, that is, the comets of the years 1532, 1577, 1585, 1607, 1618 and 1652, crossed the ecliptic and the equator.

From this, then, it is quite clear enough that some comets have crossed, or will cross, the said circles, while others have not lasted, and will not last in future, long enough to be able to reach them. Some, too, travel beneath the poles on such a path that they can by no means reach the said circles. This could also easily have been shown by more examples, had accurate observations not been lacking; we must therefore rest content with these. Now, however, it is time to come to our own comet and to inquire at what time, namely, it crossed both the equator and the ecliptic, above all since it has been more than sufficiently demonstrated in what place, and in what manner, that crossing took place.

As for the equator, it is gathered without any effort that the comet did cross it between December 20 and 23; but the question is on precisely what day and at what hour this happened. That, however, is accomplished without great trouble: namely, by resolving only one triangle and finding one side, in the diagram [Schematismo] added in Section IX, page 87, and shown here again for that purpose.

In it, AB represents the equator, DC the line of the comet's path, M the comet's first appearance, made by us on December 20 at 7 in the evening, and ML its declination at that very time, 8° 41′ 14″ south. Let there be sought, then, in the triangle HLM, right-angled at L, MH, that is, the proper motion in its path up to the equator itself, given, namely, the declination LM and the side HL, which side was already found in Section IX, page 88, Calculation 1, to be 4° 27′ 45″. When, therefore, the antilogarithms of those two sides, LM and HL, are added, the result is the antilogarithm of the hypotenuse, that is, of the interval sought in the proper orbit, namely between the first observation and the equator. For example:

Diagram. An engraved figure in a ruled rectangle beside the text: a circle crossed by the straight line BA, the equator, and by the straight line DC, the comet's orbit, which crosses BA at H. From E at the top of the circle three lines descend: a curved circle of declination through O and across BA at L, down to M on DC, a straight line to I on BA, and a curved circle of declination through F to K on BA. Dotted lines join N to F and O to G; G stands where DC meets the line from E to I. M stands on DC above D. Engraver's signature at the lower right: "Autor Sculps." (the author engraved it). Every printed label is listed; none is unread.

- E (top of the circle): point
- C (upper right, on the circle): point; end of the orbit line
- "Circ. Declinat." (along the curve from E through O and L): circle of declination
- "Declin:" and "Circul." (along the curve from E through F to K, above and below F): circle of declination
- "Cometæ." (along DC, above F): of the comet

- "Orbita" (along DC, near D): orbit
- N, F, O, G (inside the circle): points; N–F and O–G joined by dotted lines
- B (left end of the equator), A (right end): points
- L, H, I, K (on the equator line BA): points
- "Æquator." (beside K, below BA): equator
- M (on DC, at the foot of the line through L): the comet's first appearance, per the text
- D (lower left, on the circle): point; end of the orbit line
- "Autor Sculps." (lower right, inside the frame): the author engraved it

Antilogarithm ML 1154
Antilog. HL 304 *Add.*
Antilog. HM 1454 — 9° 45′ 36″[230]

This many degrees and minutes, then, the phenomenon must clearly have completed from December 20 at 7 in the evening up to the equator. Now if one inquires in what interval of time the comet travelled so great a stretch of its path by reason of its proper motion, it becomes known at the same time when it crossed the equator. This, however, is done most easily from the Table of the comet's proper motion set out in days and hours, inserted in the preceding Section, page 110. In that Table, since the comet's proper motion, from December 20

[Margin: Quò tempore Cometa anni 1652 Eclipticam transiverit.] *At what time the comet of the year 1652 crossed the ecliptic.*

at 7 in the evening likewise takes its beginning, one need only investigate in it on what day and at what hour the comet completed 9° 45′ 36″ according to that continuous and correctly proportioned motion. In this way it will become clear that this happened on December 21 between 3 and 4 o'clock in the afternoon; and when the due proportional part is applied, the true crossing of the equator took place at $3^{h}\ 13^{m}\ 47^{s}$ p.m. This could also be established by a great many other examples, but we consider that superfluous. Let us therefore turn to investigating the crossing of the ecliptic.

This investigation is undertaken in an entirely similar way, except that in this matter we need a different figure: the one by which the angle of the orbit and the ecliptic was found at that time, placed in Section X, page 93, and repeated here for the sake of better understanding. In it AB denotes the ecliptic, DC the course of the comet's path, F the comet's place at its first appearance, on December 20 at 7 in the evening, and FH the interval which the comet had to traverse up to the ecliptic, and which we have now set ourselves to investigate in the right-angled triangle HKF.

Diagram. An engraved figure in a ruled rectangle beside the text: a circle crossed by the straight line BA, the ecliptic, and by the straight line DC, the

[230] a worked calculation, set as printed: a rule stands under the figure 304 and above 1454. The printed sum, 1454, is not the sum of the two figures printed above it, 1154 and 304, which make 1458; the page's figures stand.

comet's orbit, which crosses BA at H; along the circle's edge is written "Colurus … Solftitiorum." (the solstitial colure). From E at the bottom of the circle two circles of latitude rise, one through F crossing BA at K, the other through N crossing BA at I; F and N are joined by a dotted line. From E at the top of the circle a third circle of latitude runs down through the upper G, where it meets DC, to L on BA. A second G stands below BA beside the line through I. Engraver's signature at the lower right: "Autor Sculps." (the author engraved it). The letters E and G are each printed twice. Every printed label is listed; none is unread.

- "Colurus" (upper left, along the edge) and "Solftitiorum." (right, along the edge): the solstitial colure
- E (top edge) and E (bottom edge): points, each printed once
- "Circ. Latit." (upper, along the line from the top E): circle of latitude
- C (upper right, on the circle): point; end of the orbit line
- "Cometæ." (along DC, toward C): of the comet
- G (upper, where DC meets the upper circle of latitude) and G (lower, below BA beside the line through I): points
- B (left end of the ecliptic), A (right end): points
- K, I, H, L (on BA): points
- "Ecliptica" (along BA, toward A): ecliptic
- F (on DC, below BA): the comet's place at its first appearance, per the text
- N (to the right of F, on the line through I): point; joined to F by a dotted line
- D (lower left, on the circle): point; end of the orbit line
- "Orbita" (along DC, near D): orbit
- "Circ. Latit." (below F) and "Circ. Latitud." (below N): circles of latitude
- "Autor Sculps." (lower right, inside the frame): the author engraved it

In it, moreover, FK, the comet's latitude, is given, and likewise the side HK. For HI was already known from the first calculation of the angle of inclination to the ecliptic, page 95, in the preceding Section X, namely 29′ and 44″; and likewise, in the same place, IK, that is, the difference of longitudes, 9° 22′ 43″. If, then, these sides HI and IK are put into one sum, they produce that side HK, 9° 52′ 27″. When, therefore, the antilogarithms of KF and HK are added as above, there results the antilogarithm HF of the interval between the first observation and the ecliptic, in this way:

Latitude of the comet KF 30° 49′ 1″ Antilog. 15221
Side HK 9 52 27 Antilog. 1492 *Add.*
Antilog. HF 16713 32° 12′ 40″ HF.[231]

So great a stretch remained for the comet, from December 20 at 7 in the evening, up to the ecliptic itself. Now if that very interval of its path is sought accurately in the same said table of continuous proper motion, you will find

[231] a worked calculation, set as printed: the side HK is printed "9 52 27" without degree, minute or second marks; a rule stands under 1492 and above 16713.

that the crossing of the ecliptic took place on December 24 in the morning, at 5^h 21^m [?] 11^s; and this too had to be examined.

And now that both have been found in this way, the interval which the phenomenon had to traverse from the first observation, made on December 20 at 7 in the evening, up to the equator, and the stretch which it had to traverse from the said observation up to the ecliptic, and also the true time at which the comet crossed those circles, it remains for us now to construct a Table of the true motion of the comet from the intersection both of the equator and of the ecliptic. Likewise, for the sake of those who are taken with a deeper investigation of celestial things, let us now at the same time set out for all, in one view, the most diverse motions of this star, for the individual days of the whole apparition and their quarters, which we have hitherto sought so scrupulously, both in longitude, latitude, right ascension and declination, and in proper motion along its path; and so, as a supplement [mantiſſæ loco], let us add an accurate ephemeris of these motions, concluding with it this Section XI of Book I.

[Margin: Quâ ratione ſubſequens Ephemeris fuerit conſtructa.] *How the following ephemeris was constructed.*

We first investigated the latitude and longitude, and then the declination and right ascension, not only for any day of the whole duration but also for the quarters of days, so as to know all the better and more accurately the increase and decrease of our comet's motion. But we did so by an entirely peculiar method, one we have not used before. Given, namely, the angle of the orbit and the ecliptic at H, the proper motion, that is, the distance from the intersection, FH or HG, and the point of intersection H, we examined the latitude KF or LG by resolving only the one right-angled triangle HKF, with the help of the preceding figure, when the latitude is southern, or HLG when the latitude is northern. That is, when the logarithms of the said angle and of the distance from the intersection are added, there results KF or LG, the logarithm of the latitude. The longitude, however, becomes known in the same triangle: when the antilogarithm of the latitude is subtracted from the antilogarithm FH or HG of the distance from the intersection with the ecliptic, there results the antilogarithm of the arc HK, which is to be added to the point of intersection H when the latitude is southern, or subtracted when the latitude is northern.

The declinations and right ascensions are computed in a similar way, but with the help of the earlier diagram [Schematis], inserted on page 125, and by resolving the triangle HLM or HIG, given both the angle of inclination to the equator and its point of intersection, and the distance from the intersection with the equator. This, however, will become clearer from an example.

Let us therefore compute the latitude and longitude of the comet for December 20 completed, at 12 o'clock, that is, midnight, or for the beginning of December 21, reckoning from midnight. First, however, let the comet's distance from the intersection with the ecliptic be sought, and in this way.

Subtract the proper motion of 2° 30′ belonging to the completed day of December 20, taken from the Table of proper motion set out in days and hours in the preceding Section, from the comet's distance from the first observation up to the ecliptic, found on the preceding page, 32° 13′, and you will have the true distance from the intersection with the ecliptic corresponding to the given time, 29° 43′. If, on the other hand, you want the comet's distance from the intersection with the equator, you must take away that proper motion corresponding to the given time, 2° 30′, from the distance of 9° 46′, that is, the comet's distance from the first observation up to the equator. The working of the whole calculation for finding the latitude and longitude is as follows.

Distance from the first observation up to the ecliptic 32° 13′
Proper motion up to the beginning of December 20 2 30
Distance of the comet from the intersection with the ecliptic FH 29 43 Logar. 70176
Angle of the comet's orbit and the ecliptic H 74 0 Logar. 3951 *Ad.*
FK 74,127 28° 27′ *true southern latitude.*
Antilogarithm FH 14100
Antil. of the latitude FK 12,870 *Subt.*
Antilog. HK 1230 8° 58′ *Add., since the latitude is southern.*
Point of intersection H 28 34 ♉
AK 7 32 ♊ *the true longitude sought.*[232]

This example, then, shows clearly how our Table, that is, the following Ephemeris, was constructed. It should be noted, however, that the said calculation requires the angle of the orbit both with the ecliptic and with the equator, determined very accurately, and also the point of intersection of each circle, not only for any whole days of the apparition but also for their quarters, if the variation over that interval of time requires it. We did indeed seek, and also found, those angles and places of intersection precisely enough, in our judgement, as is evident from Sections IX and X, above all from the two smaller tables inserted on pages 111 and 112, in which both the angles and the places of intersection are shown for the individual days. But since there they are not yet extended to the quarters of days, we must now first set out the angles and places of intersection in the form in which we used them in constructing the Table, so that the lover of astronomy [Aſtrophilus] may be able all the more readily to compute and examine one or another example from our Ephemeris, from the very data themselves; although I would have you be quite certain that everything has been computed by us properly and most accurately. Indeed, I cannot marvel enough at how exactly everything agrees by the said method.

[232] a worked calculation, set as printed: rules stand under "2 30", above "29 43"; under 3951, above 74127; under 12870, above 1230; and under "28 34 ♉", above "7 32 ♊". The degree groups "2 30", "29 43", "74 0", "28 34" and "7 32" print no degree or minute marks; ♉ is the sign of Taurus, ♊ of Gemini. The second line's label reads "the beginning of December 20", where the prose above speaks of December 20 completed and the beginning of December 21; both as printed.

From this it is above all gathered with certainty that both the comet's proper motion and the angles of its orbit with each great circle were derived by us very exactly; otherwise, believe me, it would have been entirely in vain to deduce from them, in such order and proportion, the comet's varying position.

Table of the angles of the comet's orbit with both the ecliptic and the equator, for the individual days of the whole apparition and their quarters.

Month, day, in the current year 1652	Angle of orbit and ecliptic	Place of intersection with the ecliptic	Angle of orbit and equator	Place of intersection with the equator
December 21	74° 0′	28° 34′	63° 4′	66° 56′

233

There now follows the Ephemeris itself of the comet's true motions. The first column shows the days completed at midnight, and the hours. The second, the comet's longitude. The third, the motion in longitude over six hours. The fourth, the comet's latitude. The fifth, the motion in latitude over six hours. The sixth, the distance from the intersection with the ecliptic, both southern and northern. The seventh, the daily motion in its proper orbit. The eighth, the right ascension. The ninth, the declination. The tenth shows the distance from the intersection with the equator. In this way the Ephemeris shows abundantly how matters stood with these various motions over the whole time of its duration. Above all, one can see that some motions gradually increased and some decreased; and moreover that the comet was direct in its path, but with respect to the ecliptic always retrograde.

Ephemeris of the true motion of the comet of the year 1652, computed both with respect to the course of its path and with respect to the ecliptic and the equator, for the individual days of the whole apparition and their quarters.

[233] the table is set as printed in five ruled columns. In the first column the day number stands at the left of the cell and, from December 29 on, the hour at the right of the same cell; the rows for December 21–28 print no hour, and the rows after the first of each day print an hour and no day. The page prints the degree and minute figures without marks, under the heads "Gr.Min."; they are given here in degrees and minutes. Rules on the page separate each of the rows for December 21–28, and then each day's four rows (12, 6, 12, 6 hours). No zodiacal sign is printed in either "place of intersection" column. No label row stands below the last row.

[234]

Ephemeris of the true motion of the comet of the year 1653, computed both with respect to the course of its path and with respect to the ecliptic and the equator, for the individual days of the whole apparition and their quarters.

January: days completed, current hours	Longitude	Motion in longitude, 6 hours	Latitude	Motion in latitude, 6 hours	Distance from the intersection with the ecliptic	Daily motion in its proper orbit	Right ascension	Declination	Distance from the intersection with the equator
1 January 12[h]	20° 38′ ♉ 6′		26° 32′ *B*	0° 18′	27° 40′ *B*	1° 20′	38° 49′	43° 19′ *B*	50° 6′ *B*
a.m. 6[h]	20° 32′	0° 6′	26° 51′	0° 19′	27° 59′	1° 19′	38° 34′	43° 35′	50° 26′
noon 12[h]	20° 28′	0° 6′	27° 9′	0° 18′	28° 17′	1° 18′	38° 20′	43° 51′	50° 44′

[234] the table is set as printed in ten ruled columns. The heads of the first column read "Decembr. Die compl. Hor. curr."; the day number stands only in the first row of each day, and the other rows are labelled on the page "m." (morning), "Merid." (noon) and "v." (evening), given here as a.m., noon and p.m. The page prints the figures without degree or minute marks, under the heads "Gr.Min."; they are given here in degrees and minutes. The zodiacal sign is printed only in the first row of each day and where the longitude passes from Gemini to Taurus. The letters *A* and *B* are printed only in the first row of each day and where the value passes from one to the other; the paragraph on the preceding page describes the distance from the ecliptic intersection as "both southern and northern". In the three motion columns each figure stands on the page half a row lower, between its row and the next; each is given here in the row above it, so that it stands against the interval it begins, and the last figure of each motion column stands below the last row of the page. Rules separate each day's four rows.

January: days completed, current hours	Longitude	Motion in longitude, 6 hours	Latitude	Motion in latitude, 6 hours	Distance from the intersection with the ecliptic	Daily motion in its proper orbit	Right ascension	Declination	Distance from the intersection with the equator

235

[235] the table continues the ruled ten-column Ephemeris of the preceding page, under the same heads, with the year in its title printed "1653" and the order of the words "in prop. orb." printed "in orb. prop.". The heads of the first column read "Januarius. Die Hor. Compl.Cur."; the rows after the first of each day are labelled "m.", "Merid." and "v.", given here as a.m., noon and p.m. The figures stand without degree or minute marks, under the heads "Gr.Min."; they are given here in degrees and minutes. The Taurus sign and the letter *B* are printed only in the first row of each day. On this page the three motion columns stand half a row higher than the other columns, each figure between its row and the row above; each is given here in the row below it, so that it stands against the interval it ends. The first figure of each motion column therefore covers the interval from the last row of the preceding page (December 31, p.m.) to January 1, 12h, which the preceding page also prints, below its last row. Rules separate each day's four rows.

So that I may satisfy your curiosity all the more, my reader, here is also an accurate graphic delineation of the comet for you. In it we have shaded in, with the greatest care, both the comet's course for the individual days (and indeed for the preceding midnight) and its tail. Moreover, how it decreased from day to day, with respect to both the head and the tail; likewise what the comet's configuration with the fixed stars was on any given day; and other things of this kind: all these are clearly evident from that figure.

And so let us bring this Book I of the *Cometographia* to an end, since in these 11 Sections we have, as it were, paved the way to the subtler and greater things concerning comets, especially this comet of ours, that are to be uncovered in the books that follow. In these we shall take pains above all to find out its true seat: whether, namely, it completed its course in the air, or in the aether. Since this whole matter rests solely on parallaxes, we shall therefore investigate these too with due labour, and indeed by a most varied method. But first of all, in the following Book, we shall show in general on what grounds, with parallaxes set entirely aside, our comet proved to be celestial; and there, with the assent of the Supreme Deity, I intend to treat at sufficient length of some matters that are as pleasant as they are useful.

End of Book I. [FINIS LIBRI I.]

Diagram. A full-page engraved plate showing the course of the comet through the constellations from 20 December to 8 January. The constellations are drawn as figures over their stars. The comet's path is a single line running from the lower left up to the top centre; the head is drawn as a hatched disc at each day, with the day's figure beside it, and a tail is drawn at the heads of 20 December, 27 December and 3 January. Two graduated bands cross the plate: the ecliptic, running from the upper left down to the right, and the equator, horizontal below it. The lettering on the plate, as read:

- Title, across the head of the plate: "Course of the comet of 1652, from 20 December to 8 January, observed at Danzig by J. Hevelius." The word for "observed" is engraved [abſervatus].
- Constellations: Auriga (upper left); Perseus (upper right); Triangulum (right, above a ruled triangle drawn round its stars); Taurus (centre); Aries (right); Orion (left); Cetus (lower right); Eridanus (lower centre); Lepus (lower left).
- The comet's path, day figures from the top down: "January" beside 8, then 7, 6, 5, 4, 3, 2, 1, 31, 30, 29, 28, 27, "26 December", 25, 24, 23, 22, 21, and "20 December" at the lower end.
- Along the path line: "Orbit" below the equator and "of the comet" [?] above it.
- The ecliptic band, labelled "Ecliptic", with the numbered ticks 30, 20, 10 on the left and the sign ♊ above the band between 20 and 10; then 30, 20, 10 to the right, with the sign ♉ above the band between 20 and 10.
- The equator band, labelled "Equator", with the numbered ticks 90, 80, 70, 60, [?]0, 40, 30 from left to right.

- At the foot of the plate: "Fig. A." (left) and "The author engraved it" [Autor ſculpſit.] (right).

All the lettering on the plate was read. Three sorts are left open: the first figure of the equator tick between 60 and 40, which may be a 5 or a 6; the fifth letter of the word engraved along the path above the equator, which may be a t or an l; and the capital of the equator label, which may be Æ or A. The unnumbered ticks of the two bands and the stars carry no lettering.

Johannes Hevelius, Cometography, Book Two [JOHANNIS HEVELII COMETOGRAPHIÆ LIBER SECUNDUS.]

That the Comet Was Ethereal Is Proved from Its Motion [Cometam æthereum fuiſſe, ex motu ejus probatur.]

Every age has indeed found that the world is ruled by various opinions. Above all, among both the older and the more recent philosophers, a very great dispute about comets arose so many centuries ago and has been carried on bitterly to this day: namely, whether comets exist and move in the air, or in the highest aether. It therefore seems incumbent on us too, now that the occasion has been given, to disclose our own opinion about this comet.

[Margin: De Cometarum ſede Philoſophi inter ſe acriter diſceptarunt.] *The philosophers have disputed bitterly among themselves about the seat of comets.*

That it was entirely ethereal is demonstrated most evidently, first of all, from the fact that, while it advanced with a proper motion in both longitude and latitude, it at the same time completed the daily, or common, motion most constantly, like all the other heavenly bodies. This certainly never happens to sublunary bodies, since they are compounded of wandering and inconstant earthly matter, as can be seen plainly in the genuine aerial meteors: the flying dragon, the torch, the beam, flying sparks, leaping goats, falling stars, the burning lance, and others of this kind.

[Margin: Cometam 1652 æthereum extitiſſe, ex motu ejus evincitur.] *The comet of 1652 is proved from its motion to have been ethereal.*

Next, the comet's proper motion, from the first time of its appearance right to the end, was supremely regular and proportionate, as is clearly evident from our Ephemeris of the comet's apparent motion. For just as its longitude, from its very first rising, grew slower against the order of the signs while keeping a certain proportion most constantly, so likewise its latitude always held strictly to its course, and was never disordered, still less wandering, that is, now greater, now smaller. The daily proper motion, it is true, was not always equal (for the comet was much faster at the beginning than at the end), but it decreased from day to day. And yet, since at all times it preserved the highest regularity and a proportionate equality within that inequality, as well as the ordinary proportion of its decline; and moreover since it never showed a motion that was at intervals now faster, now somewhat slacker, and altering itself in various ways, much less one that was wandering, inconstant, imperfect and uncertain

(as our most celebrated Keckermannus [Bartholomäus Keckermann] puts it, Book VI of the *Physics*, p. 1698);

[Margin: Cometæ motus proprius, quanquam inæqualis apparuerit, regularis tamen extitit.] *The comet's proper motion, although it appeared unequal, was nevertheless regular.*

but always kept the same tenor, of a kind found in no motion under the heavens, that is, in the aerial region. The most distinguished Fortunio Lyceto [Fortunio Liceti], though otherwise wholly devoted to the Peripatetic sect, agrees, in Book VI, chapter 32, p. 405 of *On New Stars and Comets* [de novis Aſtris & Cometis]. We therefore rightly conclude that the comet existed not in the air but in the aether itself.

[Margin: In aëreâ regione ſive ſublunari perpetuò motus datur vagus.] *In the aerial or sublunary region the motion found is always wandering.*

This is confirmed all the more by the fact that the comet, with its proper motion, most constantly described a circle that was exactly a great circle, and never perceptibly departed from its orbit or deviated to one side or the other (if you separate the annual motion of the earth from the comet's motion; otherwise, towards the end of the apparition, by reason of that motion, namely the earth's, when it becomes perceptible relative to the comet's motion, the paths of comets usually seem to curve somewhat; of this phenomenon more will be said below), but always kept its regard to fixed poles and divided the sphere into two equal parts, in the manner of all the heavenly bodies. From this one may argue as follows. Whatever body moves along a great circle that bisects the sphere, keeping fixed poles, is wholly ethereal. But our comet, throughout the whole time it lasted, scarcely strayed at all from the most exact course of a great circle, and kept fixed poles. Therefore it was plainly an ethereal body.

[Margin: Cometa ſub circulo inceſſit maximo.] *The comet advanced along a great circle.*

Some of the Peripatetics, too, very gladly assent to this argument, and freely admit that Aristotle himself held no other view than that those bodies whose motion takes place along an exact portion of a great circle are in the ethereal region, and that sublunary bodies never enjoy so regular and constant a course. Among others, the most learned philosopher Fortunio Liceti expressly indicates this in Book VI, chapter 31, p. 404 of *On New Stars and Comets*: *According to Aristotle, circular motion is twofold. One is simple: it belongs to celestial things alone, and it alone can take place in a great circle. The other is circular by predominance, and is present in subcelestial things, such as the element of fire and the uppermost air, many portions of which are forcibly thrust downward by the daily motion; because of the fluidity and rarity of its matter, and because of its resistance to motion in its proper place, where it naturally longs to rest, the air receives that motion with fluctuation. Hence it comes about that whatever things are contained in the uppermost air and in the element of fire, which are carried round the centre of the world with the motion of the heaven, with fluctuation and resistance, do not have a simple circular motion made exactly in a great circle. Therefore a comet in the elements, even if it is not carried*

towards its fuel nor driven by the winds, but is drawn by a star, will not be able to move exactly along a great circle. And according to Aristotle only celestial things have an exactly circular motion, towards which they have the greatest propensity, with no resistance at all. Hence we have truly established that every body whose motion was exactly along a portion of a great circle was necessarily, in Aristotle's view, in the ethereal region. So Liceti.

[Margin: Ariſtoteles ipſe conſentit, ætherea corpora moveri ſub portione circuli maximi.] *Aristotle himself agrees that ethereal bodies move along a portion of a great circle.*

[Margin: Cometa in Elementis nunquã ex mente Ariſtotelis & Lyceti fertur per circulum maximum.] *In the view of Aristotle and Liceti a comet in the elements is never carried along a great circle.*

Seneca, too, leans towards this opinion when he says, in Book VII of the *Natural Questions*, no. XXIII: *No regular and celestial fires have a crooked course. It is proper to a star to trace out its orbit. Whether other comets have done this, I do not know; two have done it in our own age.* Indeed, not only did those two do it, but so did all those comets whose accurate observations have reached us: namely the comets of the years 1531, 1532, 1533, 1577, 1585, 1590, 1607 and 1618, and likewise our own of 1652. Nor any doubt

[Margin: Omnes Cometæ, qui aliquãtò accuratiùs ſunt obſervati, minimè vagum & tumultuoſum habuerunt iter.] *All comets that have been observed with some accuracy have had a course that was anything but wandering and disorderly.*

would there be about all the rest, provided that the astronomers [Aſtroſophi] had not neglected to measure them carefully. So it is certain, again and again, that comets do not go confusedly and turbulently, as Seneca says, but always preserve the highest regularity, even in the very inequality of their motion. This is by no means possible in a wandering body, that is, in meteors, fiery and sublunary ones, which are tossed by various winds, drawn this way and that by their fuel, or driven by the force of this or that star; on the contrary, a wandering motion must necessarily be found in such a body. For things that are in the air, as experience teaches, stray from their course without law or proportion, and have an uneven and inconstant motion.

To this, it is true, someone might object that the conclusion, namely that the comet dwells in the aether, follows correctly from the syllogism above, but that the minor premise, namely that the comet described a great circle by its motion, is undoubtedly false; for the contrary can be demonstrated without much difficulty from Tycho himself. Just as this objection does seem utterly to destroy the foundation of our whole argument, so it will also be worth the trouble to examine it more scrupulously.

[Margin: Ex Tychone haud obſcurè infertur, nonnullum Cometam motu ſuo minimè deſcripſiſſè circulum maximum.] *From Tycho it is inferred quite clearly that some comet by no means described a great circle by its motion.*

We cannot deny, indeed, that Tycho also argued from this that comets performed their motion along a great circle: that the angle of the orbit with

both the ecliptic and the equator was entirely equal to itself throughout the whole time the comet lasted, and remained of the same size. This is clearly evident from what we cited above, in Book I, Section X, p. 114, from Tycho's Book II, chapter VI, on the comet of the year 1577, p. 103. It is therefore easily proved that those bodies in which the angle of inclination, or of the orbit to the ecliptic or to the equator, is not always found the same, do not describe an exact great circle, nor divide the sphere into two equal parts, much less have fixed poles. Moreover, it cannot be denied either that the angle of our comet's orbit to the ecliptic and to the equator varied from day to day. For at first it decreased over the space of some days; afterwards, having made a station, as it were, it increased again little by little right to the end. In the same way the point of intersection did not always stay in the same place in the heavens either. At first it was carried with a retrograde motion, though a very slow one; but afterwards it acquired a direct motion [?], and one that grew faster in succession, as we showed at length and in various ways, with very great labour, in the preceding Book, Section X. Moreover, we demonstrated there just as well, from observations most worthy of trust, that the case was the same with this angle for eight other comets, and that it was at all times inconstant and variable, however differently Tycho, Snellius and Crügerus [Peter Crüger], those leading lights [Coriphæi] among astronomers, may have thought. Hence we finally conclude firmly that in all comets the said angle and the nodes are variable, and indeed not with some fixed, perpetual variation, but for the most part with a varying one: each comet, that is, exhibits an almost individual change of the angle and of the node. From this, therefore, it may safely be gathered that, since the angle is not always the same but variable, comets must necessarily move along no great circle, but along another, perhaps smaller one, or rather along a markedly winding line.

[Margin: Quibus ex rationibus Tycho ſtatueritCometam exercuiſe motum ſub circulo maximo.] *The reasons for which Tycho determined that the comet performed its motion along a great circle.*

[Margin: Autor ultrò fatetur plurimorum Cometarum angulos orbitæ & Eclipticæ, nec non nodos variabiles extitiſe.] *The author freely admits that the angles between the orbit and the ecliptic of very many comets, and their nodes as well, were variable.*

[Margin: Vt ut alii,aliter ſenſerint.] *However differently others may have thought.*

And so this argument, advanced in favour of ethereal comets, can be turned round with no trouble to draw the contrary. For whatever body does not move in a great circle of the sphere is sublunary and elemental; but comets do not advance along a great circle of the sphere; therefore comets are sublunary and elemental. The major premise is most manifestly true; and the minor is clearly proved from the variable and inconstant angle of comets demonstrated in Section X of Book I. So it would seem that the plain contrary is more probable. Rightly, does it seem? For in truth, if the matter is weighed on a more accurate

balance, the falsity of this syllogism will easily be evident: namely, that the minor premise is defective, and that its proof, which is drawn from the variation of the angle of inclination to both the ecliptic and the equator, and also from the instability of the point of intersection, is false in every respect. For however variable this angle, together with the point of intersection, may be in all comets, it by no means follows that comets nevertheless cannot describe a great circle by their motion, even though this very point seems otherwise to some. So it seemed to Tycho, concerning the comet of the year 1577, in Book II, on the comet, chapter VI, p. 96, and p. 103, and likewise concerning the comet of the year 1590, in the Letter to the Landgrave, p. 176; and no less to Snellius and Crüger, concerning the comet of the year 1618, as can be seen from the passages cited in Section X of our preceding Book. For I am thoroughly convinced that these astronomers, as will be shown more fully shortly, went very far astray in their reasoning (which, however, I wish to be said without prejudice to their honour). This is more than sufficiently evident from the wandering stars [Stellis erraticis]: it cannot be denied of them that they dwell in the aether and have an ordered path in a great circle. And yet nothing at all is more certain and true than that all the planets, too, exhibit a variable and inconstant angle of inclination, although each in an entirely different way: in some, that is, the variation of this angle is greater or smaller, and in others, likewise, faster or slower.

[Margin: Argumentum admodum fallax eſt, quod à variatione anguli orbitæ atq; Nodi petitur pro Cometarum motu vago ſeu flexuoſo.] *The argument drawn from the variation of the angle of the orbit and of the node, in favour of a wandering or winding motion of comets, is quite fallacious.*

[Margin: Vt ut inclinatio Orbitæ atque Nodus varietur, nihilo tamen ſecius motus phænomeni peragi poteſt ſub circulo maximo.] *However the inclination of the orbit and the node may vary, the motion of the phenomenon can nonetheless take place along a great circle.*

[Margin: Id quod planetis dilucidè probatur, qui pariter non perpetuò eandem inclinationem ad Eclipticam & Æquatorem retinent.] *This is clearly proved by the planets, which likewise do not perpetually keep the same inclination to the ecliptic and the equator.*

In reality, indeed, the angle of inclination is almost perpetually constant and fixed (unless later ages should change something on account of some definite anomaly); and yet as regards appearance it is very changeable and unstable. To understand this correctly, one must know that the eccentric of each wanderer [Erronis] has its own definite inclination with respect to the ecliptic. For example, in Saturn the angle at which the limits are inclined to the ecliptic is 2° 32′; in Jupiter 1° 20′; in Mars 1° 50′ 30″; in Venus 3° 22′; in Mercury 6° 54′; and in the Moon 5°. Yet in the superior planets, as also in Venus, the latitudes are now greater, now smaller than the inclination, whereas in Mercury the latitude never equals the inclination but is always smaller. For Mercury, even when it is most remote from the Sun, is always nearer to it than to the earth.

The latitude of Saturn increases up to 2° 47′, that of Jupiter to 1° 40′, of Mars to 7, of Venus to 9°, of Mercury to 5°, and of the Moon to 5° 17′. Thus in all the planets the angle of inclination, or of the orbit and the ecliptic, always varies; but (as I would have you note well) only as regards appearance, since in itself, as we have just said, it is always constant. Indeed, according to some authors, not even the Sun itself, the most orderly of all the planets, is wholly free of every variation of obliquity, or of the angle of inclination of its orbit to the equator.

[Margin: Angulus inclinationis, in quocunq; Planetâ, quantus ſit.] *How great the angle of inclination is in each planet.*

[Margin: Angulus inc inationis tanl tùm quoad apparentiam variatur.] *The angle of inclination varies only as regards appearance.*

Moreover, the nodes of all the planets, like the points of intersection in comets, are also inconstant and mobile, though in an altogether different way. In some planets this motion of the nodes is carried according to the order of the signs, in others against the series of the signs; and likewise it is faster in some, slower in others. The node of Saturn advances each year 1′ 12″ in the order of the signs, relative to the vernal equinox; that of Jupiter only 3″ in the order of the signs; that of Mars 40″ in the order of the signs; that of Venus 47″ in the order of the signs; that of Mercury 1′ 25″ in the order of the signs. But the node of the Moon is carried forward 19° 19′ 43″ each year, and that against the series of the signs; although, with respect to the fixed stars, the nodes of all the other planets also move toward the preceding signs [in antecedentia].

[Margin: Nodi Planetarum quoq; variantur; & quâ ratione.] *The nodes of the planets also vary; and in what way.*

[Margin: Nodi, quanto ſpatio quotannis promoveantur.] *How great a distance the nodes are carried forward each year.*

Something similar is found in the Sun itself, since the intersection of the ecliptic and the equator, namely the point of the equinox, is by no means immobile either, but has a definite motion, however extremely slow. From this arises that well-known precession of the equinoxes, as is known to all astronomers and lovers of astronomy [Aſtrophilis].

[Margin: De præceſſione Æquinoctii.] *On the precession of the equinox.*

Now although the nodes of all the planets, and the angles of inclination of the orbit and the ecliptic, vary and move in different ways, now increasing and now decreasing, and they appear to describe no exactly great circle of the sphere, I think nobody is so rash as not to believe, nonetheless, that the planets move in the aether, that is, in the heaven itself. It is the same with comets: although their nodes and angles of inclination are mobile and variable, comets can nonetheless be celestial, just like the other planets.

[Margin: Etiamſi Planetæ diverſimodam Inclinationem exhibeant, nihilominus tamen certum eſt eos ſub circulis moveri maximis.] *Although the planets show an inclination that differs in different ways, it is nonetheless certain that they move under great circles.*

But to go into this matter still more precisely, and to reach at last an absolute conclusion, I say that the angle of inclination, of the planets as well as of the comets, is variable and changeable not in reality but only in appearance. This comes from the fact that the planets, and likewise the comets, do not always keep the same distance either from the Sun or from the Earth, but are now nearer to the Sun, now nearer to the Earth, and now farther away. For the more the planets approach the Sun and the earth, the more the angle of inclination increases; conversely, the more they recede from the Sun and the earth, the more that angle decreases, according to the motion of each planet. But if it could happen that the comets and the planets always kept exactly the same elongation from the Sun and the earth, and their distance between the Sun and the earth never changed, then that angle of inclination too would certainly be perpetually invariable. Supposing, therefore, that the planets and the comets always kept the same distance between the Sun and the earth, the inclination itself would also be truly immobile, according to the opinion of all mathematicians. This is clearly evident above all from Kepler's *Epitome of Copernican Astronomy* [Epitome Aſtron. Copernic.], Book VI, pp. 754 and 773, where he asserts that the inclination is always constant and fixed, unless later ages should change something on account of a transposition of the ecliptic, and that the latitudes appear to increase about the limits only through approach and recession.

[Margin: Cur Angulus inclinationis Planetarum tantùm quoad apparentiam exiſtat variabilis ?] *Why is the angle of inclination of the planets variable only as regards appearance?*

[Margin: Quâ ratione variatio iſtius anguli accidat.] *In what way the variation of this angle comes about.*

[Margin: Quomodo inclinatio datur immobilis.] *How the inclination is found to be immobile.*

And so you see, my lover of astronomy [mi Aſtrophile], that there is only a visible and apparent variation and change, not a true one, both of the latitudes at the limits and of the angle of inclination, or of the orbit, of the planets and the comets. Given, therefore, that the angle of inclination is in truth stable and invariable, it follows also that the motion of the planets and the comets takes place in an entirely great circle;

[Margin: Concluditur Cometas inſtar Planetarum verſari in ſummo æthere.] *It is concluded that comets, like the planets, move in the highest aether.*

and so that the comets too, just like the planets (as we argued above), move in the aether.

Next, I would also have you note that the apparent motion of the angle of inclination in comets is not irregular and winding, but supremely ordered and regular. That is, the said angle does not become now greater, now smaller, without any law and proportion of motion, but increases and decreases proportionally, and indeed according to the elongation. Thus, as the elongation increases, that angle decreases, and conversely, as the elongation decreases, the

angle increases, as is plain to everyone from optics; so much so that in this angle a certain wonderful and most constant variation, and a supremely regular inequality, is perpetually observed. Exactly the same happens with comets, both with ours and with all those whose angle of inclination we derived anew, with care, from sound observations in Section X of the preceding Book. For it is most manifestly clear there that the motion of their angle was always no less regular and proportionate, and that, like the planets, it had a definite increase, stations and decrease, as is clearly gathered from their longitudes, latitudes, right ascensions and declinations.

[Margin: Motus anguli inclinationis apparensCometarum, ratione elongationis à Sole & Terrâ, eſt regularis & ordinatus:] *The apparent motion of the angle of inclination of comets is regular and ordered according to their elongation from the Sun and the Earth.*

Therefore, since there is almost no difference between planets and comets as regards their varied motion, whether of longitude and latitude or of the nodes and the inclination, comets as well as planets certainly move in the highest ethereal region. Accordingly, that whole latter argument, which seemed to urge the contrary, collapses entirely, while our former one, namely that comets are celestial, stands altogether unshaken; for comets, like planets, are truly carried at all times in a great circle.

[Margin: Concluditur Cometas eſſe cœleſtes.] *It is concluded that comets are celestial.*

There is a further point. We found the angle of the orbit and the ecliptic, or the equator (as can be seen plainly from Sections IX and X of the preceding Book), always like itself and varying from day to day in a certain definite proportion, from each and every observation, whether those taken at the rising, where the orbit and the vertical almost always coincided, or those at the setting, where the orbit stood almost perpetually parallel to the horizon. It is therefore quite certain that the comet had either no notable parallax at all, or at least one far smaller than the Moon's. For if the comet had had even some perceptible parallax, the said angle of the orbit and the ecliptic, or the equator, would certainly have had to come out far smaller from the observations taken at the setting, with the orbit parallel to the horizon, on account of the parallax depressing the comet toward the horizon, than from those obtained at the rising, with the orbit roughly coinciding with the vertical. But since no such variation of this angle at all was detected, and the angle was found always equal to itself, as we have just said, the comet was free from all parallax whatever, and consequently moved in the highest aether.

[Margin: Vnde pateat Cometam anni 1652 parallaxin, Lunæ parallaxi longè minorem habuiſſe, atq; ſic in altiſſimo æthere incesſiſſe.] *From which it is evident that the comet of 1652 had a parallax far smaller than the Moon's parallax, and so moved in the highest aether.*

Finally, one may also argue with probability, from its proper motion in its orbit, that our comet was ethereal, since its daily motion (and that even when it

appeared fastest) did not exceed the Moon's daily motion. This would certainly have been otherwise if the phenomenon had dwelt below the Moon. Rea-

[Margin: Probabile argumentum,Cometas ferri in æthere.] *A probable argument that comets are carried in the aether.*

son, after all, agrees in the highest degree that the farther a body is removed from the earth, or rather from its own true centre, the more slowly it moves, as happens in all the heavenly bodies. For Mercury, being nearest to the Sun, the universal centre of the planets, is also the fastest of all (except the Moon, which acknowledges another centre); but Venus, Mars and Jupiter are slower in the measure that they are farther away than Mercury, so that Saturn, the most remote of all the planets, is also the slowest of all. Nor does this contradict Aristotle himself, as can be seen in Book II of *On the Heavens* [Lib.II. de Cœlo], where he asserts that the farther each star is from the earth, the slower it is in its own proper motion.

[Margin: Planetæ quò propiùs centro Vniverſi,eò velociores ſunt.] *The nearer the planets are to the centre of the universe, the faster they are.*

Now the Moon's daily motion sometimes rises to 12, 13, 14, or even 15°, whereas the comet's greatest daily motion, namely between December 20 and 21, was only 11° 16′. Whether it was somewhat faster still on the day before, we learned nothing certain; but supposing it was faster, it nevertheless did not exceed 13 or at most 14°, as far as one can rightly conjecture from the proportion of the daily motion. Therefore the comet had a higher seat than the Moon, even at the time when it was nearest to the earth. And if we weigh its daily motion on the remaining days of its appearance, decreasing notably from day to day, and near the end smaller even than half a degree, it is not absurd to conclude that by then it had moved above Mars, whose daily motion is otherwise 31′ 27″.

[Margin: Cometa 1652, omni tempore altior Lunâ extitit.] *The comet of 1652 was at all times higher than the Moon.*

[Margin: Circa exitum remotione ſuâ à Terrâ Martem penè ſuperavit.] *Near its end, in its distance from the Earth, it almost surpassed Mars.*

Exactly the same is affirmed [?] of all the other comets too, especially of the 8 whose proper motion we were able to derive duly, in Book I, Section X, from properly made observations; for their proper motion was somewhat slower still than that of our comet. Thus the greatest daily motion of the comet of 1577 was observed to be 6°; that of the comet of 1585 only 3°; of the comet of 1590, 7½°; of the comet of 1607, barely 10°; of the comet of 1618, only 2½°; and in some it was generally smaller still. Hence, by Aristotle's own reasoning, all of them dwelt far above the Moon.

[Margin: Ex ſententiâ Ariſtotelis diverſi Cometæ extiterunt cœleſtes.] *According to Aristotle's view, various comets were celestial.*

Therefore not only this comet but all the others whose sound observations have reached us agree with the heavenly bodies and the planets, and indeed with the Sun itself, in all their properties: both as regards the common motion

and the proper motion in their orbit, which is as regular as can be, always keeping the due proportion of speed, slowness and slackening; and also as regards longitudes, latitudes, right ascensions and declinations; then in having mobile nodes and a definite angle of inclination that is mobile and variable in an orderly way, and so a most constant course, in the manner of the stars, in a great circle; and finally, as regards the daily motion, in always showing it slower than the Moon's. Since this is so, we certainly conclude, again and again, that not only our comet but the other comets too existed in that most spacious theatre of the stars, and by no means in the elementary world, in which no such harmonious motion, perpetually constant on every side, is found.

[Margin: Autor deniq; concludit,certis ex rationibus, omnes Cometas fuisſe æthereos.] *Finally, the author concludes for definite reasons that all comets were ethereal.*

End of Book II. [FINIS LIBRI II.]

Johannes Hevelius, Cometography, Book Three [JOHANNIS HEVELII COMETOGRAPHIÆ LIBER TERTIUS.]

On the Parallaxes, Derived by a Rougher Method, of Comets Supposed to Have Their Seat in Various Regions of the Air [De Parallaxibus, datâ, in diverſâ aëris regione Cometarum ſede, rudiori methodo deductis.]

When everything said in the preceding Book has been properly weighed, I do not doubt that all seekers of the truth, to a man, unless they altogether prefer the authority of the Peripatos [Peripati] and are governed by preconceived opinions, will admit with me that it has been shown clearly enough, even from the arguments adduced above alone, that the comet must rightly be counted among the heavenly bodies. Nevertheless, both for the sake of the Peripatetics, that they may at last come to their senses, and for the sake of the astronomers, that they may be made all the more certain of the sounder opinion, let us go further, and, applying the greatest diligence, let us explore whether any parallax at all, and then how great a one, belongs to our comet, so that at the same time we may rightly and accurately track down its true place and its distance from the earth, which is otherwise attempted in vain without parallaxes. This very thing will be all the more welcome to mathematicians and astrosophers [Aſtroſophis] who look more deeply into the heaven, the less anyone among the very many writers on this comet (with due respect, however, to the reputation of all) has yet attempted this task as its dignity and necessity require, and happily accomplished it. And yet the whole matter hangs on this, and the whole dispute between the astronomers and the Peripatetics can be settled only once the parallaxes of comets have been soundly investigated and sufficiently demonstrated.

[Margin: Vlteriore inveſtigatione Autor detegere proponit,utrùm aliqua, & quãta Com. 1652. competat parallaxis ?] *By further investigation the author*

proposes to discover whether any parallax, and how great a one, belongs to the comet of 1652.

[Margin: Absq; parallaxi nullo modo verus Cometæ locus innoteſcit.] *Without parallax the true place of the comet can in no way be known.*

Hence we wonder that, after the noble Tycho, that marvel among astronomers, scarcely anyone among so many most distinguished and most learned men, both of the previous century and of our own, has come forward who, in the same way as Tycho himself, by so many routes, overcoming so many windings and rocks, with such skill and labour, has derived the parallaxes of even a single comet from the one that arose in 1577 up to now, even though in 1618 there appeared one whose like has scarcely shone since the creation of the world. Far be it from us, however, that I should accuse any one of them of negligence of any kind. For most comet-writers [Cometographorum] mostly occupy and enslave their minds with vain astrological predictions and divinations, built on no solid foundations, not so much for the sake of truth and of advancing the study of the stars, as for the sake of gain and of pleasing and entertaining common people; so that they very rarely investigate the nature and motion of the sublime ethereal bodies; and even if, at the very most, some-

[Margin: Nemo adeò ſollicitè ut Tycho Brahæus parallaxibus operam dedit.] *Nobody has devoted himself to parallaxes as carefully as Tycho Brahe.*

[Margin: Cometographi, plerunq; vanis prædictionibus ſe ſe oblectant.] *Comet-writers mostly amuse themselves with vain predictions.*

times wish to, they are scarcely accustomed to investigating these things properly, that is to say, by the geometrical route. Indeed, to penetrate and unravel each and every thing about comets with exactness is, just as it is nearly the most difficult of all matters in astronomy, so also a task that needs the greatest subtlety, labour and industry: this, however, as is their custom, the astrologers for the most part shun. We would therefore be unjust toward such men if we demanded anything more of them than they are able to deliver. But most of the rest, very learned men and true astronomers, have left this labour undone, I believe, for no other reason than that they were equipped neither with adequate instruments nor with other people's observations, most worthy of trust, accurate and many-sided; and where these are denied, it is certainly vain, even for Tycho himself, to produce anything worthy of praise. For the observations of comets from which parallaxes are to be derived are not carried out with common, toy-like and childish instruments, still less with the naked eye or merely by stretching out a thread, since the matter is extremely subtle and sometimes turns on the very smallest quantities. Rather, the instruments must likewise be the best of all, of proper size, made of solid material, entirely free of every fault, and likewise divided most finely and most accurately into single minutes and parts of minutes. Moreover, it is required above all that in making celestial observations we should also be extremely circumspect and should always attend to the highest precision that can ever be achieved, as those know especially who have worked more diligently in this arena [hoc in

pulvere] and have been well trained in this art by the constant practice of many years.

[Margin: Cometarum negotiumomnium ferè eſt difficillimum.] *The business of comets is nearly the most difficult of all.*

[Margin: Niſi juſtè elaboratis inſtrumentis fide dignisſimas obſervationes acquiſiveris,nihil quicquam certi circa parallaxes elicies.] *Unless you have obtained observations most worthy of trust with properly made instruments, you will draw nothing at all certain about parallaxes.*

[Margin: Requiſita perquàm necesſaria ad peragendas obſervationes.] *Requirements that are absolutely necessary for carrying out observations.*

Since this is so, and since, by the favour of the Divine Power, I had obtained with my most solid instruments — namely the large azimuthal quadrant, the sextant and others — not a few most exquisite observations, relying on which I was confident that I could draw the parallaxes of this comet out of such deep hiding into the light, I set about this work with the greatest eagerness, and did not fear this Herculean labour in the slightest: however great the difficulty that presented itself in tracking down the comet's parallaxes, and far greater, certainly, than with other new phenomena, such as fixed stars, which entirely lack proper motion and stand in a perpetually fixed place. For our comet was endowed at first not only with a very swift proper motion, but also with an unequal one (although one that grew successively and proportionally slower). Then, during the whole time it lasted, it was not possible to observe its passage through the meridian even once: both because of the comet's excessive altitude around its rising and the inconvenience of the observatory, and because in its last days it never reached the meridian. All of this certainly produced no ordinary perplexity in the intricate business of the parallaxes.

[Margin: Multò difficiliùs Cometas, quàm novas Stellas calculo perveſtigare.] *It is much more difficult to track down comets by calculation than new stars.*

For this reason it can scarcely be told, indeed it would scarcely be credible to any but those more experienced in these matters, how much labour and time it cost before merely all those things that are necessarily required in advance for calculating the parallaxes had been investigated by due geometrical reasoning: namely, for each of so many observations, the true time from the altitudes and azimuths of the fixed stars; and from the comet's altitudes and azimuths, its longitudes, latitudes, right ascensions and declinations; and from the distances of various fixed stars from the comet, likewise the longitudes, latitudes, right ascensions and declinations; then, no less, for all the observations, the true place of the Sun and the distance of the com-

[Margin: Quænam initiò ab autore exploranda fuerunt.] *What the author had to investigate at the outset.*

et from the Sun; in turn, the angle between the comet's orbit and the ecliptic, both from the altitudes and azimuths of the comets and from the distances; besides this, the point of intersection of the said orbit and the ecliptic, and the comet's proper motion for each day; finally, from the right ascensions and

declinations, the angle between the comet's orbit and the equator, together with the point of intersection of these same circles — to say nothing of very many other things which have been left out of this work for the sake of brevity.

And although all these things have already been investigated by us with great care, as is clear from the first Book, and reduced to tables, nothing more has yet been accomplished than that the first solid foundation for deriving the parallaxes, and the road for getting that far, has been very well laid. It follows, therefore, that with GOD we should gird ourselves for the principal business itself, the parallactic one, for whose sake we have toiled through all that went before.

But before the parallaxes of this comet are derived more artfully, the aim is first to demonstrate to everyone by a plainer and simpler method, through diagrams set before the eye, that the comet was situated far above the Moon; and to demonstrate it above all to those who have been little devoted to such most intricate and most abstruse astronomical matters, or who are unable to follow those subtler methods of investigating parallaxes. For I am convinced that in this way not only those who are wholly ignorant of mathematics, but even those entirely without any learning, provided they have some knowledge of letters, can be brought to understand and grasp that the comet was subject to no parallaxes at all, or to very small ones, and indeed to believe most firmly that it existed in the highest aether.

[Margin: Autor primùm conſtituit rudiori modo demonſtrare, Cometam ſupra Lunam incesſisſe.] *The author has resolved first to demonstrate by a rougher method that the comet moved above the Moon.*

But let us approach the matter itself. It should be known, then, that the comet, as the journal of observations shows, on December 26 at about 5^{h} in the evening formed a straight line with the two stars in the foot of Perseus, and stood off from the Heel by nearly as great a distance as this star stands from the other star in the foot; and that it also kept roughly this straight line through nearly the whole night, until the comet set, except that little by little it tended more and more towards Circius, and moved off a little farther upward from the Heel.

[Margin: Cometa cum duabus in pede Perſëi Stellis conſtituit lineam rectam.] *The comet formed a straight line with two stars in the foot of Perseus.*

From this observation, therefore, which of all the others most struck the eyes of the onlookers, learned and unlettered alike, and which at the same time seems to serve our purpose exceptionally well, we shall first examine the parallaxes by a rougher route, and shall show to the eye that the comet in no way existed in the elementary region. And to make the matter all the clearer, we shall consider the comet as if it had dwelt in that region of the air in which meteors are otherwise generated; and indeed, for better understanding, in the highest part of that same region, namely at a distance of 20 German miles, 15 of which make one degree. Yet, as has been shown clearly enough in its place, even the twilight itself, or the highest air, which according to the greater chorus

of philosophers consists of the lightest and subtlest vapours of all, scarcely rises to 13 miles in height. Indeed some, like Kepler on p. 33 of *De Cometis*, assert that the region of the air, or atmosphere, ends right at the highest summits of the mountains: hence on Mount Olympus in Asia and on the snowy peaks of Peru one can no longer live, for want of that breath which we call air, and which we cannot do without inhaling.

[Margin: Cometa in inferiori aëris regione ad 20 ſcilicet mill. exhibetur.] *The comet is presented in the lower region of the air, namely at 20 miles.*

[Margin: Crepuſculum vix ad 13 mill. aſcendit.] *Twilight scarcely rises to 13 miles.*

But supposing, though not granting, that the comet was 20 miles distant from us, the question is how great and of what kind the difference of aspect [diverſitas adſpectus], or parallax, would have been for the comet. This will indeed soon become most evident if we draw our phenomenon, set in one straight line with the two little stars in the foot of Perseus, at different times and at different altitudes, with the parallaxes appropriate to that same distance from the earth: namely, how it would have behaved with respect to those two stars in the said position; and that it could not always have kept a straight line through the whole night, as was observed by everyone everywhere, but rather that it would have shown a momentary variation of its distance with respect to these little stars, and at almost every moment would have formed different triangles, and these so varied that it could scarcely be put into words. But the matter will become clearer with a diagram. And by means of this Parallactic Table, which we chose to construct for this purpose for every two degrees of altitude of any phenomenon and for widely differing distances from the earth, the lowest of which is assumed to be only two, and the highest 10,000 semidiameters of the Earth [Semid. T], anyone may at once and with no trouble at all perceive, at all these distances from the Earth, the parallax corresponding to any given distance and altitude of a phenomenon. And conversely, given the parallax of altitude of any phenomenon, the distance of any phenomenon from the earth may also at once be evident. Since this table is not only very useful for this purpose of ours but can also readily be applied hereafter to very many other matters, I have gladly chosen to insert it here, especially since no one up to now has ever constructed one for so great a distance of a phenomenon from the earth.

[Margin: Mira diverſitas adſpectus Comet. 20 mill. à terrâ remoti.] *The remarkable parallax of a comet 20 miles distant from the earth.*

[Margin: Tabula Parallactica.] *The Parallactic Table.*

Table of Parallaxes of Altitude [TABULA PARALLAXIUM ALTITUDINIS.][236]

Degrees of apparent altitude	2	3	4	5	6	7	8	9	10	12	15

[236] the head of the table, spanning the distance columns, reads "At a distance from the centre of the Earth, in semidiameters of the Earth" [AD DISTANTIAM A TERRÆ CENTRO SEMIDIAMM. TERRÆ.]. The figures 2 to 15 heading the columns are those distances. The left column is headed "Degrees of apparent altitude" [Grad. Viſæ Altitud.]; each distance column is headed "Gr. M." (degrees, minutes), and each cell gives the parallax of altitude in degrees and minutes. The rows are printed in groups of three, divided by rules.

Degrees of apparent altitude	2	3	4	5	6	7	8	9	10	12	15

[237] the head of the table reads, as on the preceding page, "At a distance from the centre of the Earth, in semidiameters of the Earth" [AD DISTANTIAM A TERRÆ CENTRO SEMIDIAMM. TERRÆ.], and the figures 20 to 70 heading the columns are those distances. The columns for 20 to 45 are headed "Gr. M." and give degrees and minutes; the columns for 50 to 70 are headed for minutes and seconds (printed "M.Sec.", "M.Sec", "Mi.Se.", "M Sec", "Mi.Se.") and give minutes and seconds. The rows are printed in groups of three, divided by rules.

[238] the head of the table reads, as on the preceding pages, "At a distance from the centre of the Earth, in semidiameters of the Earth" [AD DISTANTIAM A TERRÆ CENTRO SEMIDIAMM. TERRÆ.], and the figures 80 to 180 heading the columns are those distances. Every column is headed "M. Se." and gives the parallax of altitude in minutes and seconds. The left column is headed "Degrees of apparent altitude" [Grad. Viſæ Altitud.]. The rows are printed in groups of three, divided by rules.

[239] the head of the table reads, as on the preceding pages, "At a distance from the centre of the Earth, in semidiameters of the Earth" [AD DISTANTIAM A TERRÆ CENTRO SEMIDIAMM. TERRÆ.], and the figures 190 to 1000 heading the columns are those distances. Every column is headed for minutes and seconds (printed "M.Sec.", "Mi.Se." and "M.Sec") and gives the parallax of altitude in minutes and seconds. The left column is headed "Degrees of apparent altitude" [Grad. Viſæ Altitud.]. The rows are printed in groups of three, divided by rules.

[240] the head of the table reads, as on the preceding pages, "At a distance from the centre of the Earth, in semidiameters of the Earth" [AD DISTANTIAM A TERRÆ CENTRO SEMIDIAMM. TERRÆ.], and the figures 1100 to 10000 heading the columns are those distances. The eight columns 1100 to 3000 are headed "M. Se." and give the parallax of altitude in minutes and seconds; the eight narrow columns 3500 to 10000, whose distances are printed turned sideways, are headed "Se." and give it in seconds only. The left column is headed "Degrees of apparent altitude" [Grad. Viſæ Altitud.]. The rows are printed in groups of three, divided by rules. At altitude 88 the 1300 column prints no minute figure.

25	62° 20′	69	20° 30′

[241] the table stands at the right of the first paragraphs. It is set in two blocks side by side, divided by a double rule; in each, the column headed "Apparent altitude" [Viſæ Altit.] gives the altitude in degrees, and the column headed "Parallax, degrees and minutes" [Parall. Gr.M.] gives the parallax. The left block passes from the horizon directly to 3°: no rows for 1° and 2° are printed. The rows are printed in groups of three, divided by rules.

Apparent altitude	Parallax	Apparent altitude	Parallax
26	61° 27′	70	19° 32′
27	60° 33′	71	18° 33′
28	59° 38′	72	17° 35′
29	58° 44′	73	16° 36′

45	43° 43′	89	0° 58′

[Margin: Hac in diſtantiâ Cometa locum in horam mutaſſet.] *At this distance the comet would have changed its place hour by hour.*

1. Let there be, then, in the accompanying diagram B: *a*, the following star of Perseus's left foot; *b*, the heel; *c*, the comet; *e*, the place of the comet if it had lacked its proper motion; while *f* is the place of the comet that it acquired by its proper motion, to the left. This was the first observation, with the heel at an altitude of 22°, at about 5 in the evening, in the eastern quadrant, when the comet first came into view after sunset on December 26 and formed an entirely straight line with the two in Perseus's foot. Now, to an altitude of 22° and a distance of 20 miles there corresponds, from the accompanying parallactic table, a horizontal parallax of 65°. The true place of the comet at that time was therefore in reality higher by that many degrees, namely at *c*; for all parallax depresses, and the more so, the lower the altitude of the phenomenon.
2. In the second observation, with the heel at an altitude of 30°, at about 6 o'clock, the comet's parallax *f c* comes to 58°. Since this is 7° less than the former, the comet in this station also comes out higher, so that it now forms an acute-angled scalene triangle with the said stars, where an hour before it had formed an entirely straight line.

[Margin: Quanto intervallo Cometa remotus extitiſſet à calcaneo hor. ſeptimâ.] *How great an interval separated the comet from the heel at the seventh hour.*

3. In the third observation, at 7 in the evening, with an altitude of 40°[242] and a parallax of 48°, the triangle appears still more acute; at the same

[242] the degree mark is printed as a small superior sort shaped like a 6

time the distance from the heel is thirteen times greater than in the first observation, and consequently the comet itself is rendered higher by 26°.

[Margin: Ad 40 grad. diſtantia dicta crevisſet, in remotioneCometæ à terra 20 mill: hor. circ. 10] *The said distance would have grown to 40 degrees, at the comet's distance of 20 miles from the Earth, at about 10 o'clock.*

4. In the following observation, with an altitude of 50° and a parallax of 39°; likewise in the fifth observation, with an altitude of 60° and a parallax of 29°; and also in the sixth observation, with an altitude of 64°, that is, on the meridian itself, and a parallax of 25½° — as the altitude increased and the parallax decreased, the triangle became ever more acute, and the distance of the comet from the heel greater. Thus in the said sixth observation, that is, at the greatest elevation, the comet was already 40 degrees away from the heel (whereas in the first observation, at 5 o'clock, it was not yet two degrees distant), and stood some degrees beyond the zenith towards the north, although those two little stars in fact appeared some 20 degrees below the zenith.

[Margin: Quâ ratione vicisſim diſtantia Cometæ à Calcaneo decrevisſet.] *How, in turn, the distance of the comet from the heel decreased.*

5. From this sixth observation, that is, from the greatest altitude of the heel, as the altitudes in the western quadrant decrease in turn in the same proportion, the parallaxes grow again. From here up to the 4th hour of the morning, namely the 10th observation, the triangles again become gradually shorter, and in part more obtuse, and the distances of the comet from the heel diminish: exactly the contrary of what happened in the eastern quadrant from the second observation to the sixth.

[Margin: Inſolens Cometæ phænomenon.] *An unusual phenomenon of the comet.*

6. In the eleventh observation, however, at 5 in the morning, with the heel at an altitude of only 20 degrees, a quite different and notable change is found. For since the parallax there is two degrees greater than in the first observation, the triangle, which until now had appeared upward together with the comet, is now seen turned downward, and its apex reaches as many degrees below the straight line *a b d* as the parallax of this eleventh observation is greater than the parallax of that first observation. So that in the space of a single hour the comet, with the two stars so often mentioned, now an upright acute-angled triangle, now in turn, out of a triangle, a line quite

Diagram. Engraved plate, "Fig. B", showing the comet against the two stars in Perseus's foot at twelve successive observations through one night, set as twelve columns side by side, divided by dotted verticals. In each column the two stars (drawn as asterisks) stand at the foot and the comet (a hatched disc, lettered *c*) above or below them, joined to each star by a straight line. A solid horizontal line runs across the head of the plate, with an *e* on each column's dotted vertical just below it and an *f* above a dotted line just over it (column

1 has an *e* but no *f*). Up each column, set sideways, is the parallax for that observation, and beside each comet its altitude; below the columns stand the hour and the number of the observation. In column 1 the comet stands at the foot, in line with the two stars; from column 2 to column 6 it rises higher and the triangle grows more acute; from column 7 to column 10 it comes down again; in columns 11 and 12 it stands below the two stars, the triangle pointing downward. Every label on the plate was read; none is supplied from the text.

- Column 1: *e*; "Parall. 65°." *Parallax 65°*; "Altit. 22°." *altitude 22°*, *c*; *a*, *b* (no *d*); "Hor. 5." *5 o'clock*; "1."

straight, and now also, at once, out of the straight line, a somewhat less obtuse-angled inverted triangle, would form.

7. This can likewise be seen in the twelfth and last observation, at 6 in the morning (in which the parallax for the altitude of the heel is given by the table of parallaxes as 74°), except that here the comet makes still further towards the horizon, descends below the straight line *d b a*, namely by nine degrees, and again forms a more acute and much longer triangle.

[243] the plate gives the altitude here as 48°; the text, p. 192, gives 40° for the third observation, with a parallax of 48°.

[244] the point after "Altit" may be a colon.

[Margin: Qualis admiranda Cometæ ad 20 mill. remoti extitisſet apparitio.] *What a marvellous appearance the comet would have made, removed to 20 miles.*

[Margin: Diverſitas adſpectus ratione latitudinis & declinationis.] *The parallax with respect to latitude and declination.*

You see, then, from this sketch of the parallaxes for the various altitudes of the heel, or of the comet, in how many different ways the phenomenon would have changed its place from its rising to its setting, even if it had been 20 miles distant from the Earth and higher than the very matter of the twilights. Not only would it have left that line with the two said stars as quickly as possible; it would also have formed by far the most varied triangles, both upright and inverted, now acute-angled, now obtuse-angled. Moreover, it would have shown far more widely differing distances with respect to those stars, variable from minute to minute by almost a whole minute, as is clear from the parallactic table, and sometimes 40 degrees greater than it in fact had. From this it necessarily follows that the latitudes and declinations too (to say nothing of the longitudes and right ascensions, so as to avoid greater confusion) would have been increased and diminished in a remarkable way in that same night — and indeed by as much as 48½ degrees, since the difference between the greatest parallax, namely 74°, and the least, 25½°, equals exactly that many degrees. But to put it more clearly: even though in the first observation, at 5 o'clock, with the heel at an altitude of 22°, the latitude was in reality only 12° 46′, nevertheless after five hours had passed, at about 10 in the evening and the meridian, the latitude would by reason of the parallax have appeared as 54°. Likewise the declination, which was then only 31° 19′, would in a like space of time have grown to 73°. Furthermore, from the sixth observation to the 12th, that is, after 8 hours had passed, in the western quadrant, the latitudes and declinations would in turn have decreased by fully 48½. So at every minute of time, indeed at every moment, the said latitudes and declinations would have been highly variable — especially if those skilled in these matters had happened to observe the comet with instruments at the time. Indeed, why instruments? This sudden variation and change could have been noticed with the naked eye by anyone at all, even those wholly unlettered, provided they knew one or two little stars.

[Margin: Solido argumento demonſtratur Cometam ann. 1652 in æthere extitiſſe.] *It is shown by a solid argument that the comet of the year 1652 was in the aether.*

If, therefore, our comet had been in the highest region of the air, even at a distance of 20 German miles (to which not even the thinnest exhalations of all can ascend, still less those denser ones from which, according to the opinion of the Peripatetics [Peripati], comets are generated), it would certainly have produced parallaxes as monstrous and dreadful as we have said and demonstrated, and with them unheard-of and incredible variations, both of the said triangle of the comet with those two stars in the foot of Perseus and of the latitudes and declinations, continually from its rising to its setting. In fact, however, since it can be clearly demonstrated by all our observations, and indeed by

those of all others taken in any place whatever, that on December 26 the comet had none of these diversities and sudden changes at all, but through the whole night (as we have already indicated above more than once) almost a straight line with those two little stars it constantly kept, and that it varied its distance from the little stars just mentioned very little indeed, by no more than 1½ degrees, upward in accordance with its proper motion; and likewise that its latitudes and declinations increased continuously and proportionally by only two degrees — then it is certainly proved from this, and quite rightly, that the comet was not in the air, within whose bounds, by the admission of the natural philosophers [Phyſicorum], all those evaporations are contained, but much higher, and indeed, as will become still clearer from what is to be said below, in the aether itself.

[Margin: Rationi prorsùs abſonum eſt, ullum unquamCometam adeò horribiles ſaltus, ratione longitudinis & Aſcenſ. R. exercuiſſe.] *It is wholly contrary to reason that any comet ever made such dreadful leaps in longitude and right ascension.*

And so we have not the least doubt that from what has just been said it will have been shown amply, and more than enough, to everyone — especially to anyone weighing the matter a little more carefully — that in no way did either our comet, or any other comets ever, shine forth that made such wondrous leaps and led such utterly monstrous dances. Nevertheless, so that the mask may be stripped more and more from the Aristotelian philosophy and the truth be revealed more fully, I shall demonstrate what further, utterly absurd changes and parallaxes the comet would have shown at a distance of 20 miles from the Earth; how it would likewise have made its longitudes and right ascensions not only continually variable in a certain fixed manner, but now greater, now smaller; and how on each night it would have shown itself direct, stationary and retrograde, and then would have spun round continually at very great speed. As a result its distances from the fixed stars would have changed more and more. What is more, the comet would every night have joined itself to quite different fixed stars, far apart from one another both in longitude and in latitude. This is clearly found from the globe itself, if you correctly mark on it only the comet's hourly vertical parallaxes from the preceding diagram B, and so duly measure the longitudes, the latitudes and its various approaches to the fixed stars. For then you will notice that the parallaxes always extend in the vertical circle, according to its azimuth, towards the opposite side, that is, towards the point opposite the azimuth. For example: in the first observation, when the comet's vertical circle stood roughly in the east, that is, at about the 90th degree of azimuth counted from the meridian, the parallax tends towards the west. In the third, fourth and fifth observations, however, with the azimuth slightly changed, the parallax, in the vertical circle itself, now more southerly, became a little more northerly than the west; so that in the sixth observation, with the comet on the meridian itself, the parallax was entirely northern. But as the comet, with its azimuth, withdrew more and more from the meridian towards the west, the parallax gradually became more easterly; finally, in the

tenth, eleventh and twelfth observations, with the comet wholly in the west, the parallax faced entirely to the east. But all this will be perceived more openly and clearly from the accompanying figure, drawn in that manner from an artificial globe. This very thing could indeed also have been computed and demonstrated without difficulty, in various ways, by geometrical calculation; but we shall dispense with that labour on this occasion. For these parallaxes and differences of the anomalies do not amount to a few minutes and degrees but run to some tens of degrees, so that there is no need for such precision and care.

In this diagram, then, ♈ ♋ the ecliptic; *c c c c* etc. the apparent place of the comet in those twelve observations, distinguished by numbers; those lines hidden, running from *c* towards the ecliptic, give the apparent latitudes of the comet that the comet showed in each observation and at each altitude by reason of the parallax.

Diagram. An engraved figure set into the text, the figure drawn from an artificial globe that p. 196 announces: the comet's apparent places over the night against the stars, with the ecliptic as a straight line across the foot, Cancer's sign ♋ at its left (east) end and Aries's sign ♈ at its right (west) end. A dotted arc carries the comet's hatched discs, eleven of them numbered 2 to 12 and one unnumbered, standing just above and to the left of 11. From each disc a dotted vertical falls to the ecliptic; each is labelled sideways with a latitude and ends at a point marked with a longitude. Stars are drawn as asterisks, some named and about a dozen unnamed. Every label on the figure is listed below as read; none is supplied from the text. Constrained readings: "Caput Eric[[h/k]]tonii.", "Lucid. in de[[x/c]]t. pede", "H[[æ/œ]]di.", "Occidens[[./:]]" and the right-hand longitude "1[[8/♉]]".

- Comet discs: "c", "6"; "c", "5"; "c", "7"; "4", "c"; "8", "c"; "3", "c"; "9", "c"; "2", "c"; "10", "c"; "c" (unnumbered); "11", "c"; "12" (no *c*).
- Star labels: "In crure Casſiop." *in the leg of Cassiopeia*; "In flexura ad Coxas" *in the bend at the hips*; "Caput Eric[[h/k]]tonii." *the head of Erichthonius* [?]; "Extrema in Sup. ped. A." *the outermost in the upper foot of A.* (A. unexpanded); "Lucid. in de[[x/c]]t. pede" *the bright one in the right* [?] *foot*; "Alamac." *Alamak*; "Capella." *Capella*; "H[[æ/œ]]di." *the Kids*; "In crure Persei." *in the leg of Perseus*; "Calcan." *the heel*; "In pede Per." *in the foot of Perseus*; "Cauda" *the tail*.
- Latitudes, set sideways along the dotted verticals: "Latitud. 52°."; "Latitud. 48½°."; "Latitud. 28°."; "Latitud. 37°."; "Latit. 19°."; "Latit. 38°."; "Latit. 27°."; "Lat. 20½°."; "Lat. 15½°."; "Lat. 13°."; "Lat. 12°."; "6°." *latitude 52°, 48½°, 28°, 37°, 19°, 38°, 27°, 20½°, 15½°, 13°, 12°, 6°*.
- On the ecliptic, left to right: "Ecliptica." *the ecliptic*; "♋"; "Oriens." *east*; "24 ♊"; "18 ♊"; "12 ♊"; "2 ♊"; "25 ♉"; "23"; "21 ♉"; "20 ♉"; "16"; "15"; "13 ♉"; "Ecliptica:" *the ecliptic*; "Occidens[[./:]]" *west*; "1[[8/♉]]"; "♈" — *24° Gemini, 18° Gemini, 12° Gemini, 2° Gemini, 25° Taurus, 23, 21° Taurus, 20°*

Taurus, 16, 15, 13° Taurus; the last figure is 18, or 1 with the sign of Taurus [?].

- Below the ecliptic: "Cometæ" and "Longitudo." *longitude of the comet*; at the lower right, "Aut. Sculpsit." *the author engraved it*.

The points, however, at which those latitudes end on the Sun's path show the comet's apparent place in the ecliptic by longitude, both for each observation of that night of December 26 and for the altitudes of the comet given above. The comet's altitude in the first observation is 22 degrees; in the second, 30 degrees; in the third, 40 degrees; and so on.

[Margin: Cometa in diſtantiâ 20 mill. aliquot horarum ſpatio conſpicitur Retrogradus, Stationarius & directus, & quidem confuſo ordine.] *A comet at a distance of 20 miles is seen, within the space of a few hours, retrograde, stationary and direct, and in confused order at that.*

So anyone now examining the whole drawing carefully will see plainly that the comet, at that distance of 20 miles, from the first observation, taken at about 5 in the evening at an altitude of 22°, when it formed a straight line with the two in the foot of Perseus, became retrograde, and its longitude increased just as its latitude, on the contrary, decreased; so that around the fourth observation it would have appeared as if stationary. From this 4th observation, in turn, it would have become direct, advancing in the order of the signs, its latitude gradually increasing up to the sixth observation and its longitude all the way to the seventh. Then, having made its station, the latitudes would have diminished and the longitudes increased continuously, the comet being retrograde in its turn. And from this it is rightly concluded that the comet, on the same night, from 5 in the evening to 6 in the morning, would have been twice retrograde, twice stationary and once direct, and at the same time would have described a pseudo-circle [pſeudo-circulum] about 33 degrees in diameter and about 104 degrees in circumference — if, that is, it had had its seat in the aerial region, even placed in its highest part, at 20 miles. What is more, within the space of thirteen hours the comet would have varied its latitudes by as much as 40 degrees and likewise its longitudes by as much as 41 degrees (granting, too, that it could have stayed above the horizon so long, although this will be wholly denied a little later), now in the order of the signs, now against it, and no less wonderfully its distances from the heel, as is plain to anyone from the table below. The first column gives the individual observations; the second, the time of the observation; the third, the altitudes of the heel; the fourth, the comet's longitudes; the fifth, the comet's latitudes; and the sixth shows the comet's distance from the heel.

[Margin: Quomodo Cometa eâdem nocte bis retrogradus & Stationarius factus eſſet, ſi in ſupremâ aëris regione extitiſſet.] *How the comet would have become twice retrograde and stationary in the same night, if it had been in the highest region of the air.*

[Margin: Hoc in ſitu Cometa breviſſimo temporis intervallo longitudines & latitudines ad 40 grad. variat.] *In this position the comet varies its longitudes and latitudes by as much as 40 degrees within a very short interval of time.*

[Margin: Quibus Stellis fixis ſe asſociasſet, unâ eâdemq́; nocte.] *The fixed stars it would have joined in one and the same night.*

But to pursue this matter further, I think I should point out at the same time that the comet, at the said distance of 20 miles, with its longitudes and latitudes varying so rapidly and so enormously, would likewise have joined itself to different fixed stars in one and the same night. So in the second observation it would no longer have stood near those two stars in the foot of Perseus but, after the space of one short hour, not far from the head of Medusa; in the third observation, beside Alamak, that bright star in the southern foot of Andromeda; in the fourth observation, near the brighter one in the right foot of Andromeda; in the fifth observation, its course bending away from the star in the bend at the hips of Cassiopeia, it would have appeared very close to the star in the leg of Cassiopeia; in the seventh observation it would have been not far from the head of Erichthonius; next, in the eighth observation, heading towards Capella; in the ninth observation, passing the Kids; in the eleventh observation, joined once again to those two stars in the foot of Perseus; and finally, in the twelfth observation, the comet would have been seen overhanging the tail of ♈.

[Margin: An ejusmodi enormem imò ſummè admirabilem motum Cometa unquā exhibuerit? etiā penes ipſos Peripateticos eſto judicium.] *Has a comet ever shown such an enormous, indeed supremely marvellous, motion? Let the judgement rest even with the Peripatetics themselves.*

If, then, the comet is placed in the atmosphere, it is more certain than certain that it would have been subject to such changes and vicissitudes as we have now demonstrated to the eye from firmer foundations, and so would truly have had a motion that was wandering, varied, vagabond, tortuous, irregular and in no way proportionate. But of what sort this abortive motion, the leaping beyond all measure, the lawless dance, the erratic gyration, the winding and

the marvellous metamorphosis would have been, let our opponents themselves judge. I, for my part, am entirely convinced that no one will be so bold and so brazen-faced, unless he wishes to make himself a laughing-stock to the whole world, as seriously to ascribe such a motion to our comet. For not only could this have been clearly detected on December 26, when the comet clung quite firmly all night to the two stars in the foot of Perseus; the comet would also have performed these most intemperate and immoderate leaps on every single night, and these always unique, with wholly dissimilar courses, circuits (because from day to day it was gradually rising by its proper motion) and approaches to one fixed star after another, as you should note well. Indeed, I am not afraid to declare that of all the comets noted and observed since the beginning of the world by chronologers, historians, philosophers and mathematicians (and yet the number of those observed from the year 480 before the birth of Christ up to now amounts to at least 156), not a single one has ever appeared that produced such unusual and abnormal anomalies of motion.

[Margin: Autor ſibi perſuadet nullum prorsùs Cometarum à mundo condito illuxiſſe,qui talem vagabūdum & tortuoſum motumexercuerit.] *The author is convinced that not one of the comets since the creation of the world has shone that performed such a wandering and tortuous motion.*

[Margin: QuotCometæ ab anno 480 ante Chriſtum apparuerint.] *How many comets have appeared since the year 480 before Christ.*

[Margin: Iterum iterumque comprobatur Cometas univerſos nullo tempore in aëreâ ſubſtitiſſe regione.] *It is proved again and again that comets, all of them, have at no time stood still in the aerial region.*

Since, then, on December 26, from the very setting of the Sun almost until its rising, the comet continuously formed a straight line with the two in the foot of Perseus, apart from that variation of its proper motion; since, in the manner of the wandering stars, it showed longitudes and right ascensions that were supremely proportionate, retrograde and continuously decreasing, but latitudes and declinations that were always increasing, as our Ephemeris of the comet's apparent motion, appended to Book I, Section XI, attests; and likewise distances that grew gradually greater from the fixed stars it was moving away from, and little by little smaller from those it was approaching; since it by no means made such a rapid leap and, in a word, produced no such abortive and horrible parallaxes, but advanced with a supremely proportional and most regular motion beneath a certain definite portion of a great circle of the sphere (as I reported more fully above, in the preceding Book) — it is assuredly proven by evident arguments that both our comet and all the others (since they, no less than ours, were not subject to such enormities) were placed not in the air or atmosphere, even if you extend it to 20 German miles, but much higher.

[Margin: Cometa in aëre exiſtens vix duas horas ſupra horizontem commoratur.] *A comet in the air stays scarcely two hours above the horizon.*

[Margin: Cometa 1652 certo tempore per 17 hor. ſupra horizontem extitit.] *The comet of 1652 was, at a certain time, above the horizon for 17 hours.*

From here I come to the point we promised just now: that the comet, at the given distance of 20 miles from the earth, could not have stayed above our horizon for two hours, but would have had to be carried from rising to setting within two hours, with a motion that would certainly have been most rapid (to say nothing of its having performed such enormous motions and leaps in so tiny an interval of time). Yet it cannot be denied that it rose and set together with the fixed stars — on December 26, namely, together with those in the foot of Perseus. For I myself observed the comet more than 10 hours above the horizon at that time: in the evening at 4^{h} 30^{m}, when it first came into view, it was already elevated 35°; and in the morning at 2^{h} 30^{m}, when the last observation was made, it was still 30° from the horizon. And the comet was not only above our horizon for 10 hours but, to speak more accurately, was visible for 17 hours together with the two little stars in the foot of Perseus.

But to demonstrate clearly that at that distance the comet could not have stayed above the horizon even for two hours: let A B F D be a semicircle of the earth, A its centre, whose semidiameter A F is 860 German miles. Likewise let A C G I H E be the semicircle of the atmosphere, whose radius A G, or A H, is 880 miles, that is, 20 greater than the earth's. In the two right-angled triangles A F H, A F G, therefore, two sides are given, A G (or A H) and A F; the arc F H and F G is sought, or the angle F A H. If this is doubled, you will have the whole space that the comet completed above the horizon, or how long it could have appeared to us stationed at F.

[Margin: Demonſtratur Schemate & Calculo nonpotuisſeCometam ultra duas integras horas ſupra horizontem videri.] *It is demonstrated by a diagram and a calculation that the comet could not have been seen above the horizon for more than two whole hours.*

Diagram. An engraved figure in a plate-mark set into the text at the left of the measure: two concentric semicircles on a common straight diameter, the inner one the earth and the outer one the atmosphere, as the text describes them. The outer semicircle runs from E at the left end of the diameter through L, H, I and G to C at the right end; the inner one from D through F to B. A is the common centre on the diameter. A vertical line rises from A through F to I; a straight line runs from H to G across the top of the inner semicircle at F; straight lines run from A to H, from A to G and from A to L. Every label on the plate is listed below as read; none is supplied from the text. L is not named in the text of this page.

- On the outer semicircle, left to right: "E"; "L"; "H"; "I"; "G"; "C".
- On the inner semicircle, left to right: "D"; "F"; "B".
- On the diameter: "A" (the centre).
- Below the diameter: "Oriens." *east* (between D and A); "Occidens." *west* (between A and B); at the lower right, "Aut. ſculps." *the author engraved it*.

Logarithm of the side A F, the semidiameter of the earth, 860 — 245341
Logarithm of the hypotenuse A H, of the atmosphere, 880 *S.* — 243042

There remains the antilogarithm of the angle F A H — 2299. Its arc is 12° 14′ 20″.

[Margin: Magnitudo circuli parallactici.] *The size of the parallactic circle.*

[Margin: Quare Cometa neutiquam in aëre extiterit ? Fuisſet namq; ad 31 Decemb. prorsùs nobis inconſpicuus.] *Why was the comet by no means in the air? For until December 31 it would have been wholly invisible to us.*

Consequently, since the comet could neither have stayed above the horizon longer than $1^h\ 37^m\ 55^s$ nor, while visible, have completed more than the arc H I G of 24° 28′ 40″, it is rightly inferred from this, too, that it would have had to complete that whole circumgyration, or pseudo-circular leaping, which I mentioned above, in a quite similar space of time. The reason is evident: the diameter of that parallactic circle, in figure B above, is only a little greater than the arc H I G, or the diameter of the circle of appearance [circuli apparitionis]. And if we weigh the matter a little more finely still, and compare the diameter of the parallactic circle, of 33 degrees, with the arc of duration H I G, of 24° 28′ 40″, it follows absolutely, since the former is greater than the latter, that in that configuration the comet would have been wholly invisible to us and to everyone else until December 31; and only on the 31st, when it acquired a greater northern latitude, namely of 25 degrees, and from the vertical point of ou- rs was only 12° 14′ 20″ distant, would it have appeared on this horizon of ours (though somewhat sooner for those to the south, because of the lower elevation of the pole, and later by as much for those to the north). Yet this is most manifestly false, and contrary in every way to the observations. For not only did the comet shine continuously from the 20th, rising and setting at D and C — that is, on the rational horizon, which it always claimed for itself as its visible horizon — and not at G and H; but also, moving especially about the equator itself, it rose and set together with the other stars beside which it then stood; and likewise it cut the heaven entirely into two equal parts, namely at C E, and not into two unequal parts, G and H. Therefore, since entirely similar things have been found in all the other comets that have been faithfully recorded, all of them, together with this one of ours, were certainly not in the air. For the air can never be bisected in this way, because it is too near; but the heaven, since it is very far from the earth, and the earth is quite tiny in relation to the heaven, can be divided most fully into two equal parts — as is shown still more plainly by the construction set beside this.

[Margin: Denuò demonſtràtur Cometas eſſe æthereos.] *It is shown once again that comets are aetherial.*

Let the inner circle be the earth, the middle one the atmosphere, and the outer one the aether. Thus, from F on the earth's surface, a phenomenon is found to rise at M and set at N, since the aether, or heaven, is far enough from the earth, and the terrestrial globe bears a very small ratio — indeed almost none — to the distance of the aether. At C and E, however, we notice nothing at all from F, because of the bulging convexity of the earth and the very near distance of the phenomenon; and also because of the quite perceptible ratio between

the semidiameter of the earth and the distance of the atmosphere. Hence the whole hemisphere M O N comes into view for those stationed at F, and the whole heaven is entirely bisected; whereas of the aerial hemisphere C G H E only a small portion, G I H, is seen, which is much less than half. This is clear from the figure, even though no due proportion of the circles has been kept in it.

Diagram. An engraved figure in a plate-mark set into the text at the right of the measure: a large circle (the aether, as the text describes it) on a horizontal diameter from N at the left to M at the right, with O at its top; inside it, on the same diameter, a middle circle (the atmosphere) meeting the diameter at E and C, with H and G on its upper arc and I at its top; and an inner circle (the earth) meeting the diameter at D and B. A is the common centre on the diameter, and F is at the top of the inner circle. A short line runs through F from H to G; straight lines run from F to N and to M, and from F down to E and to C. A small arc is drawn between D and A. Every label on the plate is listed below as read; none is supplied from the text. The text names a pole L, which is not on this plate.

- On the large circle: "O" (top); "N" (left end of the diameter); "M" (right end of the diameter).
- On the middle circle: "I" (top); "H" (upper left); "G" (upper right); "E" (left, on the diameter); "C" (right, on the diameter).
- On the inner circle: "F" (top); "D" (left, on the diameter); "B" (right, on the diameter).
- On the diameter: "A" (the centre).
- At the lower right: "Aut. ſculp[?]." *the author engraved it* — the last letter before the point is undecided between s and long ſ.

[Margin: Cometa in aëre degens nullâ ratione poteſt fieri perpetuæ apparitionis, & quare ?] *A comet dwelling in the air can by no means become one of perpetual apparition; and why?*

[Margin: Id quod ſimul cum fixis oritur & occidit, id nullâ ratione eſt aëreum.] *Whatever rises and sets together with the fixed stars is by no means aerial.*

Besides these, another absurd consequence concerning the comet should also be noted: namely, that it could by no means at all have become one of perpetual apparition, as cannot be unclear from the preceding diagram. For it has already been proved that nothing whatever below H meets the eye — much less something that lies under the pole L, a point far below H. Therefore, since here at Danzig the comet was of perpetual apparition from December 28 right up to its departure — as I found with my own eyes, and it was also observed elsewhere by others — it is once again rightly inferred that the comet was not aerial. There is the further point that, together with the fixed stars, by the common motion (leaving aside on this occasion that other motion, the pro- per one), it advanced day by day, and that it also set together with those stars with which it had risen, as has already been stressed several times. For this reason Fortunius Lycetus [Fortunio Liceti], although otherwise most devoted

to the Peripatetic school, says rightly and shrewdly: that which moves with the motion of a star exists in the aether, and not in the air — as he deduces at length in *On Comets and New Stars* [de Cometis & novis Aſtris], Book V, Chapter XLV. And that an exhalation carried round in the uppermost air moves in a circle with a preternatural, accidental motion, one that is not wholly uniform, nor absolutely simple, nor exactly circular.

[Margin: Quanta parallaxis exoritura fuerit,exiſtente Cometâ in aëre; ſi nimirùm in diverſis regionibus animadverſus fuisſet.] *How great a parallax would have arisen if the comet were in the air: that is, if it had been noticed in different regions.*

These things indeed show abundantly enough what we should think about our phenomenon. Yet so that beginners, and those who are less practised in this astronomical dust, may learn these difficult and inherently obscure matters the more thoroughly and penetrate them more exactly, and so be better able to grasp the subtler parallaxes that I intend to discuss a little later, it will be useful, I think, to examine this subject more fully. We should investigate what kind and what size of difference in the parallax [diverſitatis adſpectus] the comet, existing in the air at that distance of 20 miles, would have produced, if it had been observed at the same time here at Danzig and at the same time in other places, whether southern or northern — that is, under different elevations of the pole (leaving aside for now the difference in the longitude of the places); and that it would not have been visible everywhere (as in fact it was) near the same fixed stars at the same time (setting aside also that difference of meridians).

[Margin: Obſervatio die 26 Dec. circa Cometam Dantiſci habita.] *The observation of the comet made at Danzig on December 26.*

For this purpose of ours the observation already brought forward by us earlier will serve no less well — the one made on the 26th, when here at Danzig the comet came into a straight line with the two stars in the foot of Perseus. But let us look at the very note on that observation, inserted on p. 8 of Book I: At about 6^{h} in the evening, the comet formed an almost straight line with the two fixed stars in the foot of Perseus; yet they were not at an entirely equal spacing from one another. For when the comet was observed more carefully, even with the naked eye, its centre stood from the heel at less, by ⅕ part, than the distance of the stars from each other. So the distance between the comet and the heel was estimated at about 1° 45′, the interval between the heel and the following star of the left foot of Perseus being given as 2° 10′.

[Margin: In quibusRegionibus Cometa in lineâ rectâ cum binis fixis inpede Perſei obſervatus.] *In which regions the comet was observed in a straight line with the two fixed stars in the foot of Perseus.*

[Margin: Quantam adſpectus diverſiſitatem inter Pariſios & Dãtiſcum Cometa, in diſtantiâ à terrâ 20 mill. exiſtens peperisſet.] *How great a parallax between Paris and Danzig the comet would have produced, if it had stood at a distance of 20 miles from the earth.*

This very same phenomenon appeared on the same day, in the evening, also at Königsberg [Regiomonti], Copenhagen [Hafniæ], Münster [Monaſterii], Leiden [Lugduni Batavorum], Brussels, Paris, and Digne [Diniæ] in Provence in France, as well as elsewhere in Europe. Meanwhile, however, let us compare with our Danzig observation only one of these, the Paris observation supplied by the most distinguished Bullialdo [Ismaël Boulliau], our most highly respected friend, deferring the rest to a stricter examination shortly; and so, by comparing these two with each other, let us demonstrate how great a parallax between Danzig and Paris [Lutetiam] the comet would have produced at the given altitude of 20 miles, and how enormously far from its Danzig station it would have appeared at Paris.

[Margin: Obſervatio Pariſienſis.] *The Paris observation.*

[Margin: Cometa aëreus neutiquã ſimul Pariſ. & Dant. rectum poſitum cum binis ſtellis Perſei obtinere potuiſſet.] *An aerial comet could by no means have held a position in a straight line with the two stars of Perseus at Paris and at Danzig at the same time.*

Boulliau describes this Paris observation as follows, on p. 12 of his observation [ſuæ obſerv.] published at Paris in the year 1653: *On December 26, with Aldebaran at an altitude of 35° 23′, at 6^h 16^m, the two stars of the left foot of Perseus, and the comet, were in the same straight line, the comet being nearer to the heel than to the other star, and more northerly and more westerly than the heel itself.* Likewise: *For quite a long time the comet and the two stars were in one straight line, and around 9^h the comet seemed to have passed beyond it by not much.* So he writes. You see, then, entirely the same position relative to those two stars in the foot of Perseus, both at Danzig and at Paris, at about the same hour, held by it. Yet this could in no way have happened if the phenomenon had been in the aerial region, as will become clear from what is about to be said.

Let A be the centre of the earth, B D L E its surface, F C G the atmosphere, I H K O the meridian of the starry heaven, C the comet, D Danzig, and L Paris [Lutetia Pariſiorum]. I say that the comet, standing on the meridian of Danzig near K, the little stars in the foot of Perseus, would by no means have shone beside them at Paris at the same time. Rather, removed into the northern quarter H — namely 126 degrees from those two stars, that is, in Hercules, near the Northern Crown — it would in reality have lain hidden at that time below the horizon of Paris, so that it would then have been wholly invisible to the people of Paris. But the matter will become clearer by a trigonometrical calculation, although on this occasion we shall use only a rather rough one, reserving more accurate numbers for their proper place.

Diagram. An engraved figure in a plate-mark set into the text at the right of the measure: a large semicircle (the meridian of the starry heaven, as the text describes it) on a horizontal diameter from O at the left to I at the right, with H on its upper arc and the engraved word "Meridianus." along the arc to the right of H. At the upper left of the arc stands K, with two small six-pointed stars just below it, unlettered. Two small concentric semicircles stand on the

same diameter about A: the outer one (the atmosphere) meets the diameter at G and F, the inner one (the earth) at E and B. C is on the outer small arc at its upper left; D is on the inner arc to the right of C, and L on the inner arc to the left, below C. A straight line runs from H through C down to L, and another from K through C down to D. Dotted lines run from C to a point m and from L to a point n, and a dotted line runs from near n down to A. Every label on the plate is listed below as read; none is supplied from the text.

- On the large semicircle: "H" (top, right of centre); "Meridianus." *meridian* (along the arc, right of H); "K" (upper left), with two unlettered star marks below it.
- On the diameter, left to right: "O"; "G"; "E"; "A" (the centre); "B"; "F"; "I".
- Near the small semicircles: "C" (on the outer arc, upper left); "D" (on the inner arc, right of C); "L" (on the inner arc, left); "m" and "n" (italic, at the ends of the dotted lines, between C and L).
- At the lower right: "Aut. ſculp[?]." *the author engraved it* — the last letter before the point is undecided between s and long ſ.

[Margin: Elevatio Poli Pariſienſis & Dantiſcana.] *The elevation of the pole at Paris and at Danzig.*

First, we are given the latitude of the place at Danzig, that is, the elevation of the pole at D, of about 54° 23′, and that of Paris, L, according to Boulliau, of 48° 51′. The difference is therefore 5° 32′, namely the distance D L between Danzig and Paris. Half of this, m L, or the angle m A L or n A L, will be 2° 46′. Since the hypotenuse A L is also known — the semidiameter of the earth, namely 860 — the side L n is found in the plane right-angled triangle, by logarithms, in this way: the sum of the logarithms of the hypotenuse and of the angle opposite the side sought is the logarithm of the side sought.

Second, from the same angle and the hypotenuse L A, the semidiameter of the earth, 860, the side A n results. For the sum of the antilogarithm of the angle and the logarithm of the hypotenuse makes up the logarithm of the side sought. And when the side A n is subtracted from A C (which consists of the earth's semidiameter and the atmosphere), C n remains.

[Margin: Quantus angulus Parallacticus ſit inter Lutetiam & Dantiſcum, Cometâ exiſtente in aëre.] *How great the parallactic angle is between Paris and Danzig if the comet is in the air.*

Third, in the triangle C n L, from the two sides C n and n L that enclose the right angle, the semiparallactic angle n C L is found. For the logarithm of the greater side, subtracted from the logarithm of the lesser, leaves the mesologarithm + of the smaller angle, whose complement is the greater angle sought. If this is doubled, the whole parallactic angle D C L that we are seeking becomes known.

Logarithm of the angle n A L, 2° 46′ — 303097
Logarithm of the hypotenuse A L, 860 — 245341 A.
Logarithm of the side L n — 548438 — 41½ *German miles*

Antilogarithm of the angle n A L, 2° 46′ — 117
Logarithm of the hypotenuse A L, 860 — 245341 A
Logarithm of the side A n — 245458 — 859 *miles*, A n. *Subtracted from* 880 *miles*, A C
Logarithm C n — 616582 — 21 *miles*, C n.
Logarithm L n — 548438 *Subtracted.*
Mesologarithm of the half-angle of parallax n C L — 68144 — 26° 50′
Its complement to 90 — 63° 10′
Therefore the whole angle of parallax D C L, *or its vertical angle* K C H — 126° 20′

By so many degrees, therefore, the comet would have stood away at Paris from its station on the meridian of Danzig, K, towards the north at H, because Paris lies further south than Danzig.

[Margin: Evidenti argumento iterum corroboratur Cometas extra ſphæram noſtrã vaporoſam verſari.] *A clear argument confirms once again that comets dwell outside our vaporous sphere.*

But it has never been found, either in our comet or in other true comets, that at the same time two different observers in different places, however far apart, noted so great a difference and parallax, and that one of them saw the comet in the south and the other in the north, removed more than 126 degrees from the first station. It therefore remains most true that comets are raised far above the atmosphere.

[Margin: Ex Regiomontanâ obſervatione quoq; comprobaturCometam fuiſſe in æthere.] *From the Königsberg observation, too, it is proved that the comet was in the aether.*

This is proved no less clearly from the observations of places much nearer together: namely our own at Danzig and the Königsberg observation of the most distinguished Linemanni [Albert Linemann]. He saw the comet on the same evening, of December 26, near the foot of Perseus, as can be seen from his *Letter* [Epiſtolâ] printed at Königsberg: *On December 26, at* 5^h 15^m *in the evening, the comet stood in an entirely straight line with the two little stars of the foot of Perseus, Z and o of Beyeri [Johann Bayer]; but in such a way that the comet, lying further to the right, was somewhat nearer to the heel than the foot itself was.* Just as here at Danzig and at Paris.

[Margin: Differentia Meridianorum inter Regiomontum & Dantiſcum.] *The difference of meridians between Königsberg and Danzig.*

[Margin: Elevatio Poli Regiomontana correcta.] *The elevation of the pole at Königsberg, corrected.*

But let us see how great a parallax would have arisen between Danzig and Königsberg (places whose difference of meridians is found to be only 7′, and their true distance only 14 miles) at the same distance of the comet from the earth, 20 miles. The investigation is entirely the same as the previous one, except that it rests on other data.

The elevation of the pole at Königsberg is very nearly 54° 43′, according to both Tycho and Linemann, and by no means 55° 8′, as Kepplerus [Kepler] wrongly recorded, or 54° 21′, as Longomontanus did. The difference between the Danzig and Königsberg elevations therefore comes out at 20′; half of it is 10′, whose

Logarithm n A L — 583999
Logarithm of the hypotenuse A L 860 — 245341 A.
Logarithm of the side L n — 829340 — 3 *miles*.
Antilogarithm of the angle n A L — 0
Logarithm of the hypotenuse 860 — 245341 A.
Logarithm of the side A n — 245341 — 860 A n
880 A C
20 C n
Logarithm C n — 621461 S.
Logarithm L n — 829340
Mesologarithm of the half-angle n C L — 207879 — 7° 8′
The whole parallactic angle — 14° 16′

[Margin: Angulus parallacticus inter Dantiſcum & Regiom.Cometâ verſante in diſtantiâ 20 mill.] *The parallactic angle between Danzig and Königsberg if the comet is at a distance of 20 miles.*

Consequently, according to this calculation, the comet ought to have appeared not in a straight line with both stars in the foot of Perseus, as it did here at Danzig, but 14 degrees further from the heel, and lower by as much towards the horizon, since Königsberg lies further north than Danzig. And hence, on the evening of December 26, while the comet stood in a straight line with the foot of Perseus here at Danzig, it would have shone 5° below the Pleiades — wholly against Linemann's observation.

[Margin: Quot milliaribus diſtet Regiomontum à Dantiſco.] *How many miles Königsberg is from Danzig.*

[Margin: Elevatio Poli, & differentia Merid. Dinienſis.] *The elevation of the pole, and the difference of meridians, at Digne.*

[Margin: Enormis admodùm parallaxis longitudinis inter Diniam & Dantiſcum; Cometa ſi detur in aëre.] *An utterly enormous parallax of longitude between Digne and Danzig, if the comet is supposed to be in the air.*

Since, then, so great and so widely varying a parallax arises between Danzig and Königsberg — places so close together, only 14 miles apart in a straight line — if the comet is in the air, how great indeed will it be between Danzig and Digne in Provence, the residence of that most celebrated man Gassendi, whose elevation of the pole is only 44° 6′, so that the difference of meridians is 10° 17′; especially if the parallax of the longitude of the places is computed at the same time (which is easily derived on the same basis, if in place of the difference of latitude you put the difference of longitude, and in place of the meridian the equator), and the other parallaxes are then added — namely of altitude, longitude, latitude, right ascension and declination. Good God, what kind and

how great would be the diversity of the comet's aspect, and how great the motions' confusion that would arise! If this had to be set out exactly, a good many pages would scarcely hold it. But since the more expert can easily imagine this remarkable variety for themselves even without my saying it, and the rest, too, leaving these matters aside, will by now have learned the absurdities well enough from what has been said, I restrain myself, so that our adversaries, who hold that comets are aerial, may not be made to blush any further.

[Margin: Nonnulli Peripateticorum, nimias iſtas abſurditates evitandi gratiâ, paullò altiùs Cometas attollunt.] *Some of the Peripatetics, to avoid these excessive absurdities, raise comets a little higher.*

But some of the Peripatetics abandon this opinion because of its very many inconveniences and absurdities, and raise comets somewhat higher than vapours usually ascend — namely into the clearer region of air or of fire, as Keckermann does in Book VI of his *Physics*, and others too — to 100, indeed to 1000 miles; above all, in order at the same time to free them entirely from those parallaxes that spring up [?]. Since they do so, it will not be out of place to examine the parallaxes accurately at a more remote distance from the earth as well, from that same observation of December 26.

[Margin: In gratiamPeripateticorum Autor Cometas ad 2580 mill. removet.] *As a favour to the Peripatetics, the author removes comets to 2580 miles.*

[Margin: Nec ſic poſſe inconvenientias omnes evitari, luculẽter Schemate demonſtratur.] *That not even so can all the inconveniences be avoided is clearly shown in a figure.*

It may seem, however, that we would be indulging the Peripatetics too far if we allowed them so freely to remove the comet at once from 20 to 1000 miles. Yet to make the matter still [?] more evident, let us grant that the comet is removed not only to 1000 miles but to 3 semidiameters of the earth, that is, to 2580 miles. Even so it will be perfectly plain that not even in this way can those enormous parallaxes and those remarkable changes be entirely avoided, but that the latitudes and declinations, no less, change notably with respect to the two stars in the foot of Perseus. Let us therefore take up the task again by the method already shown.

Diagram. An engraved figure in two parts, set across the measure below the text; its lettering is in an engraved italic hand. In the upper part, a horizontal ruled line runs across the figure, with a dotted line just above it. An *e* stands at the left end of the ruled line, and eleven further stations follow, each an *f* (a flourished stroke) on the dotted line above an *e* on the ruled line. The words *Verus Cometæ locus.* ("The true place of the comet") are engraved below the ruled line at its left, middle and right. From each of the twelve *e* a dotted vertical descends, with a value in degrees set along it, reading upward. Below stand twelve numbered triangles, each formed by two six-pointed stars on its base and a hatched disc (the comet) at its apex, which stands on the foot of its dotted vertical. The disc rises from the first triangle to the sixth and seventh and then falls again, and each triangle has a value in degrees set along its right

side, reading upward. Under the triangles are the words *Observatio. Quadrans Orientalis.* ("Observation. Eastern quadrant") under triangles 2–4, *Meridies.* ("Noon") under triangle 6, and *Observatio. Quadrans Occidentalis.* ("Observation. Western quadrant") under triangles 9–10, and below them a row of hour labels, one under each triangle. The lower part is a star chart. Five stars of Perseus are labelled (two stars stand by the label for the foot), and Algol is labelled at the right. Twelve hatched discs, numbered 1 to 12 but not in numerical order across the chart, are joined by a dotted line. Dotted verticals drop from the discs to a horizontal line, the ecliptic, with Cancer's sign at its left end and Aries's at its right. Values of latitude stand along the verticals, and values of longitude stand above and below the ecliptic where the verticals end. Every label on the figure is listed below as read; none is supplied from the text.

- e (12): on the ruled line, one at its left end and one under each *f*.
- f (11): on the dotted line above the ruled line, one over each *e* after the first.
- Verus / Cometæ / locus. (below the ruled line, left, middle, right): "The true place of the comet".
- Values along the dotted verticals, left to right: 18°, 16° 47′, 15°, 12°, 9° 36′, 8°, 9° 36′, 12°, 15°, 16° 47′, 18°, 19°.
- Letters at the triangles: triangle 1 *a*, *b*, *c*; triangle 2 *a*, *b*, *c*, *d*; triangle 3 *c*, *d*; triangles 4 and 5 *c*; triangle 6 *a*, *b*, *c*, *d*; triangles 7 to 10 *c*; triangles 11 and 12 *a*, *b*, *c*, *d*. In each case *c* is at the comet's disc, *a* and *b* at the base stars, and *d* beside the right side of the triangle.
- Values along the triangles' right sides, triangles 1 to 12: 22°, 30°, 40°, 50°, 60°, 64°, 60°, 50°, 40°, 30°, 20°, 10°.
- Triangle numbers: 1., 2., 3., 4., 5., 6., 7., 8., 9. [?], 10., 11., 12. The figure under the ninth triangle is a curled sort unlike the other 9s on the plate, and is read as 9 only by conjecture.
- Obſervatio. / Quadrans Orientalis. (under triangles 2–4): "Observation. Eastern quadrant".
- Meridies. (under triangle 6): "Noon".
- Obſervatio. / Quadrans Occidentalis. (under triangles 9–10): "Observation. Western quadrant".
- Hour labels, triangles 1 to 12: *Hor.* 5., 6., 7., 8., 9., 10., 12., 1½., 2½., 4., 5., 6. ("Hour 5" and so on).
- In ſiniſtro femore Pers. (upper left of the chart): "In the left thigh of Perseus".
- In ſiniſtro genu Persei. (left): "In the left knee of Perseus".
- Algol. (right, beside its star): Algol.
- In ſiniſtro crure Persei. (left): "In the left leg of Perseus".
- In pede Persei. (lower left): "In the foot of Perseus".
- Comet positions: 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12.

- Latitudes along the verticals, left to right: *Latit* 16°, 20½°, 14°, 13 and a fraction whose numerator is 1 and whose denominator is lost where a dotted line crosses it [?], 13½°, 14°, 22°, 15½°, *Latitud* 18°.
- ♋ (left end of the ecliptic) and ♈ (right end).
- Ecliptica. (above the line, left and right): "Ecliptic".
- Longitudes above the ecliptic, left to right: 29, 26, 23, 22; below it: 29½, 27, 25, 22½, 20½.
- Oriens. (below the line, left): "East"; Occidens. (below the line, right): "West".
- Tauri / Cometæ / Longitudo (below the middle figures): "of Taurus"; "Longitude of the comet".
- Autor ſculpsit. (right of the ecliptic): "The author engraved it".

In the preceding figure, let those first 12 observations be drawn at the same times and at the same altitudes as in Figure B, and let *f c* be the parallax of altitude belonging to each observation, taken from the table in this Book, p. 141. From this it is clearly gathered that at this distance of the comet, too, the appearance of that straight line would have been wonderfully changed and swung about every hour — indeed every quarter of an hour — from the very first observation to the last. And this to such a degree that at the second observation, within the space of one hour, the comet would already have become higher by a whole degree and more; at the third observation by about three degrees; at the fourth by about 6 degrees; at the fifth by 9 degrees; at the sixth by 10 degrees; and then it would have descended again in almost the same way. In this way the triangle that the comet formed with the two little stars would continually have taken on one very noticeably different shape after another.

[Margin: Cometam 2580 mill. altiùs extitiſſe.] *That the comet stood higher than 2580 miles.*

But with our comet things turned out entirely otherwise. Its latitudes and declinations by no means increased by as much as 10 degrees in an interval of 5 hours, nor did they decrease afterwards in a like space of time; rather, through the whole night of December 26, the phenomenon advanced in its orbit towards Cassiopeia, keeping the strictest proportion, while its latitudes and declinations increased meanwhile at every altitude. It is therefore again inferred, and quite rightly, that the comet was carried far higher, beyond 2580 miles.

[Margin: Mira diverſitas adſpectus in hâc Cometæ diſtantiâ.] *The remarkable parallax at this distance of the comet.*

I add that in this case the comet would have varied not only its latitudes and declinations, by as much as 10 degrees, but equally — as at the earlier given distance of 20 miles — its longitudes and right ascensions by about as many degrees, even when its proper motion is duly allowed for. No less would it have been continually wheeled about, and been now direct, now stationary, now retrograde, as is plain from the lower drawing of the preceding figure: that is, the comet would have shown itself at first retrograde up to the 4th

observation, and stationary; afterwards direct up to the 8th observation; and finally, after making its second station, retrograde in its turn. After this it would have presented remarkable changes with respect to the fixed stars. For just as at hour 5 in the evening it was joined to the heel of Perseus, so at hour 8 it would already have stood by the Head of Algol; next, at hour 10, by the left thigh of Perseus; at about hour 1, by the left knee; at hour 2, by the left leg of Perseus; and at hour 4 in the morning, by the heel once more. But all those changes at this given distance of the comet — of longitude and latitude as well as of distance from the heel, and of its visible place with respect to the fixed stars — appear more clearly at a single glance in the little table below.

The variation of the immoderate course, at a distance of the phenomenon of 2580 miles. [Variatio immoderati incesſus, ad diſtantiam phænomeni 2580 mill.]

Observation	Evening hour	Altitude of the comet	Longitude of the comet	Latitude of the comet	Distance of the comet from the heel	Approach to the fixed stars
1	5	22° 0′	25° ♉	13° *Bor.*	2°	Near the heel of Perseus.
2	6	30° 0′	23° ♉ *Retrogr.*	14° *Bor.*	2¾°	
3	7	40° 0′	22° ♉	15½° *Bor.*	4½°	
4	8	50° 0′	20½° ♉ *Station.*	18° *Bor.*	6¼°	Near Algol.
5	9	60° 0′	22½° ♉	22° *Bor.*	9°	
6	10	64° 0′	26° ♉ *Directus*	23° *Bor.*	10°	Near the left thigh of Perseus.
7	12	60° 0′	29° ♉	20½° *Bor.*	9°	About the left knee of Perseus.
8	1½ *m.*	50° 0′	29½° ♉ *Station.*	16° *Bor.*	6° *circ.*	About the left leg of Perseus.
9	2½	40° 0′	27° ♉	14½° *Bor.*	4½°	
10	4	30° 0′	26° ♉ *Directus*	13½° *Bor.*	2¾°	Near the heel of Perseus.
11	5	20° 0′	25° ♉	13° *Bor.*	2° *& paul.plus*	
12	6	10° 0′	23° ♉	12° *Bor.*	2°	

But the very opposite happened with our comet. Through the whole night, if you except its proper motion, it clung steadily to the foot of Perseus, according to the observations of everyone. Our opinion therefore stands on a firm foot.

[Margin: Quàm diuCometa 3 ſemid.à terrâ remotus potuiſſe ſupra horizontem conſpici.] *How long the comet, removed 3 semidiameters from the earth, could have been seen above the horizon.*

Moreover, the comet could not have stayed above the horizon as long as it actually did, but in that position only $10^{h}\ 2^{m}$. This, too, is plainly shown by the figure inserted on p. 152. For, given the earth's semidiameter A F, 860, and A H, made up of A F and the distance from the earth, 2580 miles — that is, 3440 miles — the angle F A H, or G I H, results.

Logarithm of the side A F, *the semidiameter of the earth*, 860 — 245341
Logarithm of the hypotenuse A H, 3440 — 106711 *Sub.*
There remains the antilogarithm of the angle sought, F A H — 138630 — 75° 31′
Therefore G A H, *or the arc* G H — 151° 2′

This angle, converted into degrees, gives 10^h 2^m — the stay, that is, above the horizon — whereas the stay was in fact found to be 17 hours. Therefore it is certain on this ground too that the comet must be raised much higher.

[Margin: Aliâ ratione convincitur, Cometam altiorem extitisſe.] *By another argument it is proved that the comet stood higher.*

This is proved more and more by the observations from different places as well. Let us therefore take our Danzig observation and that of P. Gassendi at Digne, for the same distance of the comet from the earth, namely 2580 miles. In the figure above, on p. 155, the elevation of the pole at Digne is given as 44° 6′, and that at Danzig as 54° 23′. The difference of latitude, then — that is, between Danzig, D, and Digne, L — is 10° 17′, and so the half-difference is 5° 8½′, being the angle n A L, of which:

Logarithm — 241219
Logarithm of the hypotenuse A L, 860 — 245341 *Add.*
Logarithm of the side L n — 486560 — 77 *mill.*
Antilogarithm of the angle n A L — 403
Logarithm of the hypotenuse A L, 860 — 245341 *Add.*
Logarithm of the side A n — 245744 — 857 A n

3440 A c, *from* A m, *the semidiameter of the earth*, 860, *and* m C, *the distance*, 2580

2583 C n
Logarithm C n — 135363 *S.*
Log. L n — 486560
Mesologarithm of the angle — 351197 — n C L 1° 42′
Whole parallactic angle D C L — 3° 24′, *or* H C K

[Margin: Angulus parallacticus inter Dantiſcum & Diniam,Cometâ à Terrâ remoto 3 Sem. Terræ.] *The parallactic angle between Danzig and Digne, with the comet removed 3 semidiameters of the earth from the earth.*

Consequently, the comet would necessarily have appeared to Gassendi at Digne more northerly and higher by so many degrees and minutes, while here for us at Danzig the same comet shone in a straight line with the two stars in the foot of Perseus, because Digne is more southerly than Danzig. This is flatly contrary to the Digne observation, which the said Gassendi communicated by letter to Boulliau on 1653 January 16, in these words:

[Margin: Dinienſis obſervatio Cometæ.] *The Digne observation of the comet.*

"I do not know whether I told you in my previous letter that I too, on the evening of December 26, found the comet in the same straight line as the two fixed stars in the left foot of Perseus, but a very little farther from the heel than the heel is from the other star, which is the bright one and in the front part of the foot. Be that as it may, to have

seen this phenomenon in Paris and at Digne in the same line at about the same hour is not to be made light of, for such an observation is of great moment." So he writes.

But since the comet, wherever it was observed, in whatever place, formed a straight line with the two little stars in the foot of Perseus most constantly and evenly on that same night, and in no way deviated enormously this way or that, the same follows as before: that the comet stood higher than 2580 miles.

[Margin: Alii Cometas altiores fingũt.] *Others imagine comets higher still.*

This opinion is also embraced by not a few of the Peripatetics, such as Nolthius, Claramontius [Scipione Chiaramonti] and others. Indeed, they remove comets from the earth not only to 3 but even to 8 and 9 semidiameters of the earth, that is, to 6880 and 7740 miles, so that they may extricate themselves the more readily from that net of parallaxes.

[Margin: Quantæ ſint parallaxes Cometarum in diſtantiâ 10 Semid. Terr.] *How great the parallaxes of comets are at a distance of 10 semidiameters of the earth.*

For their sake, then, let us examine whether at such an elongation, too, any parallax arises, and how great. But to be the more generous, let us grant them that the phenomena are removed to 10 semidiameters of the earth, that is, 8600 German miles, and then that they are raised even to 20 semidiameters of the earth, that is, to 17,000 — a distance much greater indeed than they themselves set. Yet we shall find that even so the parallaxes do not vanish entirely.

To that end we have added these three figures, Fig. C. In them B D marks the horizon; B C D the vertical circle from east towards west; *a* the left foot of Perseus; *b* the heel; *c* the comet, or its apparent place; *d* its true place; and *d c* the difference between the true and the apparent place, that is, the parallax. The upper figure is drawn for an elongation of the comet from the earth of 10 semidiameters, or 8600 miles; the middle one for a distance of 20 semidiameters of the earth, that is, 17,000 miles; and the lower one for an elongation of 55 semidiameters of the earth, or 47,300 miles, the Moon's mean distance from the earth. The first observation, towards the east, shows the comet in a straight line with the two fixed stars in the foot of Perseus at hour 5 in the evening, with the heel at an altitude of 22 degrees.

The second observation: at hour 6 in the evening, with the heel at an altitude of 34

The third observation: at hour 8 in the evening, with the heel at an altitude of 50

The fourth observation: at hour 10 in the evening, with the heel at an altitude of 64

The fifth observation: at hour 12, with the heel at an altitude of 60

The sixth observation: at hour 2 in the morning, with the heel at an altitude of 45

The seventh observation: at hour 4 in the morning, with the heel at an altitude of 28

The eighth observation: at hour 6 in the morning, with the heel at an altitude of 12

With these various altitudes and distances of the phenomenon thus given in these figures, very different parallaxes also result. How great they are in the first drawing, at a distance of 10 semidiameters of the earth, for each observation and altitude, as found from the parallactic table, you will have in this little table:

[Margin: Variatioparallaxeos in diſtantiâ Cometæ 10 S. T.] *The variation of the parallax at a distance of the comet of 10 semidiameters of the earth.*

Observation	Altitude of the heel	Parallax *d c*
1	22°	5° 19′
2	34°	4° 45′
3	50°	3° 33′
4	64°	2° 31′
5	60°	2° 52′
6	45°	4° 3′
7	28°	5° 4′
8	12°	5° 37′

Hence, since the parallaxes vary so very greatly among themselves from the very first observation, the comet too must continually rise noticeably and decline from that straight line, and the triangle that it forms with the two little stars in the foot of Perseus must vary very quickly, as is clear from the upper of the three figures added. So at the fourth observation, near the meridian, at an altitude of the comet of about 64 degrees and in its higher position, the triangle of that observation would have been the largest of all, and the phenomenon itself would have appeared 2° 48′ higher than at the first observation. In the western quadrant, however, as the comet gradually descends in turn, the triangles contract again. In the same way the distances from the heel, the latitudes and the declinations increased at the rising by about 3 degrees, just as they decreased at the setting. Moreover, the longitudes and right ascensions, as we have already shown above for the nearer position, would have been greatly changed; the comet now direct,

Diagram. A full-page engraved plate, Fig. C, with three figures set one above the other. Each is a half-disc: an arc rising over a horizontal base line, with the words *Ortus.* ("Rising"), *Horizon.*, *Meridies.* ("Meridian"), *Horizon.* and *Occaſus.* ("Setting") along the base from left to right. Inside each half-disc, eight numbered stations run along the arc from the rising at the left over the top to the setting at the right. At each station a hatched disc, lettered *c*, forms a triangle with two six-pointed stars lettered *a* and *b*, and a dotted vertical rises from the disc to a letter *d*. From the second station on, a further letter stands free to the right of and below the disc, near no star, usually with a small point beside it; it is read as *h* by conjecture only [?]. Inside the arc, five further numbered stations show a second hatched disc lettered *f*, with a dotted vertical rising to a letter *g*; beside it a cluster of five or six small stars, the nearest lettered *e*; from the second of these stations on, a line runs down from *f* to a letter *i* and across to *e*, closing a triangle. The three figures differ in their titles, which

give the distance from the earth, and in the shapes of their triangles. *Fig. C* is engraved in the lower figure, and *Autor ſculpſit.* ("The author engraved it") below its frame at the right. Every label on the plate is listed below as read; none is supplied from the text.

- Upper figure, title: *Diverſitas Cometæ / Adſpectus, in diſtantiâ / à Terrâ 10 S. T. / ſive 8600 mill.* — "The difference in the appearance of the comet at a distance from the earth of 10 semidiameters of the earth, or 8600 miles."
- Middle figure, title: *In diſtantiâ à Terr. 20 S.T. / ſive 17000 milliar.* — "At a distance from the earth of 20 semidiameters of the earth, or 17000 miles."
- Lower figure, title: *In diſtant. à Terr. 55 S. T. / ſive 47300 milliar.* — "At a distance from the earth of 55 semidiameters of the earth, or 47300 miles."
- Stations of the first disc, in each of the three figures: numbered 1, 2, 3, 4, 5, 6, 7, 8. Station 1 carries *d*, *c*, *a*, *b*; stations 2 to 8 each carry *d*, *c*, *a*, *b* and the free letter *h* [?].
- Stations of the second disc, in each of the three figures: numbered 1, 2, 3, 4, 5 (the upper figure prints "4."). Station 1 carries *g*, *f*, *e*; stations 2 to 5 each carry *g*, *f*, *i*, *e*.
- Along the base of each figure: *Ortus.*, *Horizon.*, *Meridies.*, *Horizon.*, *Occaſus.*
- *Fig. C* (in the lower figure, left of centre); *Autor ſculpſit.* (below the lower frame, at the right).

now stationary, now retrograde: so it would have been, with this difference, however, that in this position the parallactic circle would have grown, according to the parallaxes, to only three or four degrees, if you do not exclude the proper motion.

[Margin: Quantus in hâ[c?] diſtantiâ,circulus ſit parallacticus.] *How great the parallactic circle is at this [?] distance.*

Even so, as anyone can readily judge, this variation of appearance and this circling round would have been perceptible enough to everyone, if, that is, our comet had been endowed with such a variation and rotation. But since this was in no way detected either by us or by others living anywhere at all, what else, I ask, are we to conclude than that the comet occupied a place much higher still than 8600 miles?

[Margin: Comet. 1652 altiorem fuiſſe 8600 evidenter demonſtratur.] *It is clearly demonstrated that the comet of 1652 was higher than 8600.*

We shall be made all the more certain of this conclusion, the more plainly we are about to show that even at the said distance of the comet, 8600 miles, the parallax between different places — between Danzig and Digne, for example, that is, between us and Gassendi — does not vanish entirely.

[Margin: Ex obſervatione Dinienſi & Dantiſcanâ.] *From the observation at Digne and at Danzig.*

Let us compute that parallax by the method used above, and with the help of the figure given on p. 155, though with less labour, since most of the lines bearing on the parallactic angle, namely L n and A n, are already known from there, and only the last triangle, n C L, remains to be solved.

Since A n *is thus known,* 857 *S.*

A C 9460, *from the semidiameter of the earth and the distance of the comet there results* C n 8603

Now in the triangle n C L, from the two given sides C n and n L, which enclose the right angle, the half-parallactic angle n C L is found.

Logarithm C n — 15046 *S.*

Logarithm L n — 486560

Mesologarithm of the angle — 471514 — 0° 31′

Therefore the whole parallactic angle D C L — 1° 2′, *or* H C K.

[Margin: Angulus Parallacticus inter Dantiſcum & Diniam.] *The parallactic angle between Danzig and Digne.*

And so between Danzig and Digne the difference in the comet's position would have been so great that at Digne the comet would in no way have been seen near the heel, much less in a straight line; and yet Gassendi's observation, quoted above, testifies very clearly that this is exactly what he observed.

[Margin: Variatio motus Cometæ in diſtantiâ 20 Semid[[./:]] T[[./:]]] *The variation of the comet's motion at a distance of 20 semidiameters of the earth.*

Let us now go on to consider and work out, too, how great the parallaxes and changes the comet would have shown at an elongation of 20 semidiameters of the earth, or 17,000 miles, although terrestrial exhalations certainly cannot reach so far. The middle figure of the preceding Fig. C will serve this purpose of ours; its parallaxes of altitude, corresponding to that elongation of 17,000 miles, are shown in the following little table:

Observation	Altitude of the heel	Parallax *c d*
1	22°	2° 39′
2	34°	2° 22′
3	50°	1° 50′
4	64°	1° 16′
5	60°	1° 26′
6	45°	2° 2′
7	28°	2° 32′
8	12°	2° 48′

The variation of motion at this given distance is indeed somewhat more moderate than at the former one, nearer the earth, and the triangles likewise are somewhat smaller and more obtuse. None the less, the comet, which forms a straight line with the two stars in the foot of Perseus, would have made noticeable and conspicuous advances, or rather excursions, from the first observation up to the fourth: it would have stood about 1½ degrees higher, and more than 3 degrees away from the heel, although at about the first observation it was scarcely two degrees away. And so, in the space of 4 hours, from 6 to 10 in the evening, by a whole degree, indeed by a whole degree and a half, if the motion is added, it would have stood farther off than was actually observed, and farther than it could have advanced even by its own proper motion (which, as

can be gathered from the table of proper motion, amounted to only 45 minutes). Again, from the 4th to the 8th observation the triangles would have decreased in much the same way as the comet approached the heel, and would indeed in turn have come back to the straight line of the two fixed stars in the foot of Perseus. Hence the latitudes would have shown themselves now greater, now smaller, by up to 1½ degrees; and, owing to the inconstant longitude and the reciprocating motion, the comet would have described a parallactic circle of 1½ degrees and at the same time shown a parallax between different places. Let us now see how great that parallax comes out at a distance of 17,000 miles, namely between Danzig and Digne.

[Margin: Nec in hoc ſitu phænomena ſalvantur.] *Nor are the phenomena saved in this position either.*

Since the remaining data have already become known above, only the angle n C L remains to be computed. This time let us derive it from the table of sines and tangents, since our logarithmic table is constructed only up to 10000.

Thus there are given: the distance of the comet — 17,000 — m C
the semidiameter of the earth — 860 — A m
the side A C — 17,860 — A C
857 — A n, *found on p. 159.*
There results the side C n — 17,003

Now, therefore, as C n, 17,003, is to n L, 77 miles, so is the whole sine, 100,000, to the tangent of the angle n C L, 453, whose arc is 0° 15′ 36″; the whole angle, namely D C L or H C K, is 0° 31′ 12″.

[Margin: Abſurdum omninò Cometam in aërem rejicere.] *It is utterly absurd to relegate the comet to the air.*

Accordingly, even in this position, Gassendi should have found the comet on December 26, in the evening, at about the same hour, not in a straight line with the two little stars in the foot of Perseus but half a degree higher, towards the head of Medusa. But since things turned out quite otherwise with it, and it lacked any perceptible parallax, let the Peripatetics themselves judge, I beg them, whether it is not absurd to place the comet in the air, even at a distance of 17,000 miles.

[Margin: Cometam Lunâ altiorem fuiſſe comprobatur.] *It is proved that the comet was higher than the Moon.*

Finally, to satisfy all the more fully both our own desire and that of all other lovers of truth, we shall also show, but briefly, from the lower of the three preceding figures of the preceding Fig. C, that our phenomenon was placed higher even than the Moon, which stands at a mean elongation from the earth of 55 semidiameters of the earth, that is, 47,300 miles.

Observa-tion	Altitude of the heel	Parallax *c d* at a distance of 55 semidiameters of the earth
1	22°	57′ 16″
2	34°	51′ 48″

Observa-tion	Altitude of the heel	Parallax *c d* at a distance of 55 semidiameters of the earth
3	50°	40′ 10″
4	64°	27′ 22″
5	60°	31′ 15″
6	45°	44′ 12″
7	28°	55′ 11″
8	12°	61′ 8″

For it is evident, both from the figure assigned and from this little table of parallaxes, that even at this distance, so far from the earth, the comet is not entirely free from every parallax. This is plain both from those triangles, drawn in due proportion according to the parallaxes belonging to each altitude, and from its differing position relative to the heel, and also from its very different altitude with respect to that straight line. For from the first to the fourth observation the comet would have been seen half a degree higher than could have come about by reason of its proper motion, so that, just as above, the distances as well as the latitudes and declinations would have increased in the eastern quadrant by half a degree and more, and decreased, by contrast, in the western; add that at the same time the parallactic circle would then have appeared as 34′,

[Margin: Quantus circulus Cometæ parallacticus extitisſet ſub orbe Lunari.] *How great the comet's parallactic circle would have been beneath the lunar orb.*

and the comet would have been now direct, now retrograde, by so many minutes; whereas in fact, as the observations show — above all the table of latitude, declination, longitude and right ascension — it was carried continually against the order of the signs, and upward.

[Margin: Conſtitutio Cometæ ad Pleiadas.] *The comet's configuration near the Pleiades.*

But so as not to linger over these points too long, it should be understood that whatever we have said and explained at length, with the help of the three figures above, about the comet's position near the foot of Perseus as observed on December 26, is to be understood of any other position of the comet as well. For the sake of better understanding, however, we have likewise shown the parallax in these three drawings with the comet lying near the Pleiades, on the evening of December 24; in that position all these irregularities and reciprocations strike the eye no less, and most evidently. There, moreover, *e* represents the Pleiades, *f* the comet, *g* its true place, *i* the place of the comet at the first observation. What parallaxes the comet had at any time and at any altitude, in each of the figures about the Pleiades, the following little table shows.

Obser-vation	Hour	Altitude of the heel	Parallax, upper figure	Parallax, middle figure	Parallax, lower figure
1	6 in the evening	27°	5° 7′	2° 33′	55′ 42″
2	8	42°	4° 16′	2° 8′	46′ 27″
3	11	57°	3° 7′	1° 34′	34′ 3″
4	2 in the morning	42°	4° 16′	2° 8′	46′ 27″
5	5	15°	5° 32′	2° 46′	60′ 23″

[Margin: Si Cometa non altior Lunâ extitisset, pariter parallaxin diversorum horizontum ostendisset.] *If the comet had not been higher than the Moon, it would likewise have shown a parallax between different horizons.*

We have therefore shown, to the point of satiety, I think, and by various routes, that the comet was higher not only than the atmosphere (supposing it to extend to 20 miles), but also than a distance of 2580, 8600 and 17,000 miles, and indeed than the Moon itself, removed from us by 47,300; and this all the more clearly in that, even at this elongation, some parallax between different horizons is detected no less. Let us finally go on to seek it, too, between Danzig and Digne. Thus there are given:

Distance of the comet from the earth — 47,300 — m C

860 — A m

48,160 — A C — *from which let there be subtracted, p. 159,*

the side found, A n — 857 — *Subtr.*

The remainder will be the side C n — 47,303

Now therefore, as C n, 47,303 miles, is to 77 miles, n L, found on p. 159, so is the whole sine, 100,000, to the tangent of the angle n C L, 163, whose arc is 0° 5′ 36″; if this is doubled, the whole parallactic angle D C L becomes 11′ 12″, or the parallax H K itself.

[Margin: Cometa 1652 Lunâ longè superior.] *The comet of 1652 far higher than the Moon.*

Hence it is seen once again that at Digne the comet could in no way have been seen in a straight line with the two stars in the foot of Perseus, but must necessarily have shone there 11 minutes higher. It therefore stands unshaken that the comet carried on the regular course of its motion far above the Moon, in the highest ether: which is what was first to be demonstrated, in a general way, by these arguments.

[Margin: Parallaxes eruendimodum accuratiorem proponit Autor.] *The author sets out a more accurate method of finding parallaxes.*

But if anyone is perhaps not yet satisfied with these arguments, we shall try to weigh the matter still much more precisely and to bring everything under a more exact examination, and also to derive the parallaxes more skilfully; above all, to investigate carefully, in the most varied ways, whether our comet was subject to parallaxes, and to how great ones; and further, whether over the whole time of its appearance the parallaxes, always the same, remained; or

whether they varied continually, and how matters stood with that variation? For parallax is the one and unconquerable way to measure the distances of comets; if parallaxes are neglected and unknown, the true distance from the earth of any phenomenon, whether aerial or ethereal, is determined in no way at all.

[Margin: Nonnisi per parallaxes Cometæ locùs & distantia cognoscitur.] *Only through parallaxes are a comet's place and distance known.*

What kind of labour, and how great, it is to investigate everything thoroughly in this way and to bring it out properly, I leave to those more skilled in astronomical matters to judge. I do not doubt that all would admit it to be a work of great difficulty and immense labour, so that it is no wonder that even the ancients observed the parallaxes of comets little, as Cysat rightly says on comets, chapter 3, p. II, page 25.

[Margin: Parallaxes debitè elicere ingens labor est.] *To derive parallaxes properly is an immense labour.*

For this reason I too would almost have declined this task. But I reflected that only by this one method can that question of great moment, debated by philosophers for so many centuries past up to now, be settled altogether: namely, whether comets are generated in the highest, most limpid ether, within the regions of the planets and fixed stars, or whether, according to the Aristotelians, they move below the Moon, in the highest region of the air. I reflected, moreover, that this task (as Tycho argues in chapter VI, page 89, on comets) is the chief among those things that ought rightly to be said and inquired about comets, and without which all the rest that is put forward is defective. I have therefore taken up this charge most gladly. May God, Best and Greatest, grant that our efforts succeed as we wish, both to the glory of his name and to the advancement of astronomy and philosophy.

[Margin: Quid autorem impulerit ad parallaxes accuratiori modo indagandas.] *What drove the author to investigate parallaxes in a more accurate way.*

End of Book III [FINIS LIBRI III.]

Johannes Hevelius, Cometography, Book Four [JOHANNIS HEVELII COMETOGRAPHIÆ LIBER QUARTUS.]

On the True Parallaxes of the Comet, Both Vertical and Horizontal, Investigated by a More Accurate Method [De genuinis Cometæ parallaxibus, tam verticalibus, quàm horizontalibus, accuratiori methodo, investigatis.]

[Margin: PerParallaxes præcipua quæstio de Cometis dirimitur.] *Through parallaxes the principal question about comets is settled.*

Now that we have come, then, to this most subtle business — the one on which alone turns the hinge of the whole dispute between the astronomers and the Peripatetics about the seat of comets, and from which, once it has been duly undertaken and carried through, arises that altogether irrefutable argument

about the true distance of comets from the earth — it will not be beside the point to review briefly in advance by what method these genuine and true parallaxes, whether vertical or horizontal, may be investigated as well and as accurately as is ever possible.

[Margin: Variâ viâ parallaxes inquiruntur.] *Parallaxes are sought by various routes.*

It is certain, indeed, that the ancients and the moderns have handed down many different methods of finding parallaxes; yet of these very few can be applied, above all to phenomena of the kind that exhibit a notable proper motion, as this comet of ours did. For it is rare that the observation itself yields, at one and the same time, as many data and of such kinds as are necessarily required, because of the various reasons and various hindrances that arise during observing. Moreover, the greater part of these problems are such that they can be constructed and demonstrated much more quickly and readily than they can be carried through and computed in figures complete in every respect — above all if the parallaxes amount to only a very few minutes. Among these the second problem of Regiomontanus is, not wrongly, counted.

[Margin: ModusRegiomontani lubricus.] *Regiomontanus's method is slippery.*

Although by everyone's account it is a very subtle discovery, yet for various reasons to be given below it is by no means suited to practice and calculation. And so, in this business, something is more easily said and proposed than accomplished in the work itself with profit and with the happiest result. Tycho Brahe speaks rightly and shrewdly on this matter in the *Progymnasmata*, Book I, on the New Star of 1572, p. 518: "Not all things that hold rightly in speculation about these matters are for that reason applied in practice free from suspicion of error; especially if you build great things out of the smallest, they for the most part waste their labour." Likewise in Book II, p. 157: "There are many things which, carried into speculation, can indeed stand correctly; but if the use of practice

[Margin: Non univerſa[[,/;]] licet in ſpeculatione rectè ſe habeant,ac demonſtrari poſſint, ad praxin deducuntur.] *Not all things, though they hold rightly in speculation and can be demonstrated, are carried into practice.*

you bring to bear, then even using the most exquisite instruments and lynx-like eyes (especially where the aim is directed at slender quantities, so that the greatest are built up on them), you will fall into inextricable absurdities." Further, in a certain letter, not yet published, against Craig the Scot [John Craig]: "For many things hold very well demonstratively which cannot, however, be brought into practice so conveniently — especially if such data [dedomena] are required that a slight error in them becomes, step by step in the working of the numbers, fruitful beyond measure."

[Margin: Exiguus error : nonnunquam maximum progignit.] *A slight error sometimes begets a very great one.*

The methods of computing the parallaxes of our comet that are more accurate and safer than all others — both by reason of its motion and by reason of our

observations — are the following: 1, by the apparent and true latitudes and declinations of the comet; 2, by the apparent and true altitudes of the comet; and 3, by the apparent and true distances from the fixed stars, whether observed or derived from altitudes, azimuths and the moments of time.

[Margin: Quinam modi parallaxes eruendi omnium ſint accuratiores.] *Which methods of finding parallaxes are the most accurate of all.*

Of these, however, the last method is certainly the safest and best of all, in the opinion both of Tycho and of all the modern mathematicians. Above all, if you undertake this task through distances observed with suitable and sufficiently large instruments, the work will certainly succeed much more happily than if you carry it out from altitudes, azimuths and the time — especially if the altitudes and azimuths were obtained with some smaller instrument and you have proceeded by the route of Regiomontanus. Tycho likewise judges this rightly in his letter to Rothmann, p. 295: "The method by distances, applied in due manner, is more certain than the one taken from altitudes and azimuths, in which a scarcely perceptible error becomes very fruitful; as these things are well enough known to you, who have handled them, and who have found out how easily one errs in altitudes and azimuths, but not likewise in distances." If you wish, you may read more on this matter in the same *Epistolae Astronomicae*, pp. 96 and 99, and also what Frommius set out at length against Morin [Jean-Baptiste Morin] in his astronomical dissertation.

[Margin: Per diſtantias, modus omnium eſt tutisſimus] *The method by distances is the safest of all.*

[Margin: Procliviùs in capiendis altitudinibus & Azimuthis,quàm diſtantiis Stellarũ aberratur.] *One errs more readily in taking altitudes and azimuths than in the distances of the stars.*

For my part I freely admit, together with those most distinguished men Tycho, Longomontanus, Frommius and Riccioli, that it is very true that one errs more readily and more easily in measuring altitudes and azimuths, and also in finding the true time, than in determining distances alone. And yet it cannot be denied either that parallaxes can be computed just as accurately through altitudes, azimuths and the true time — but on this express condition: that the azimuth quadrant [Quadrans Azimuthalis] be large enough, accurately divided into minutes and parts of minutes, and properly set on the meridian line; that the time be noted most accurately with sufficient circumspection, taken not only from ordinary clocks [automata], which Tycho mostly used, but by some other, infallible means, of which various routes are now open to everyone in this age of ours; and then that each and every thing be faithfully carried out by a most practised observer. Likewise, if you choose those altitudes which are free of refractions and not very near the meridian, and azimuths which are not too far from the meridian.

[Margin: Poſſunt etiam accuratè, ſuo tamen, modo parallaxes ex altitudinibus inveſtigari.] *Parallaxes can also be investigated accurately from altitudes, though in their own way.*

If all these things are so, I have no doubt that you will find the parallaxes most correctly, just as if you had gone to seek them through the observed distances themselves — especially if you use our method, to be described shortly. This will be explained at greater length in the *Machina Coelestis*, in connection with the quadrant and sextant and their use, and will also be demonstrated in its proper place, amply and more than enough, by a good many examples.

[Margin: Tycho autori adſtipulatur.] *Tycho agrees with the author.*

Moreover, Tycho did not altogether reject this method of investigating parallaxes through altitudes and azimuths. Together with us, he held only that it is more laborious, and a matter of greater skill, to derive parallaxes from observations of this kind; and further, that the greatest diligence is needed for these observations to be duly carried out — which, however, is by no means impossible for an observer who is well practised and equipped with suitable instruments. Accordingly the most praiseworthy Tycho also very often devoted himself to these observations and used them, except that he then noted the time much more diligently, as is clearly seen from his letters, p. 295: "Where I seek the comet's parallaxes from azimuths and altitudes, there I have not omitted to note not merely the minutes but also some fraction of them in seconds." Likewise in Book I of the *Epistolae Astronomicae*, p. 95: "With the armillary machines the true place of the star is shown to the very minute, agreeing entirely with the place that is obtained either through distances by means of the sextants, or else through azimuth quadrants turned with particular skill — especially if equal care is applied on both sides during the observing."

[Margin: Tycho per Azimutha frequẽter parallaxes deduxit.] *Tycho often derived parallaxes through azimuths.*

[Margin: Ad parallaxes perfectioribus inſtrumentis opus eſt.] *For parallaxes, more perfect instruments are needed.*

From this it follows that parallaxes require supremely accurate observations, obtained with an azimuth quadrant, or a sextant, or other more perfect instruments. For if you go astray with either this instrument or that, you will look in vain for anything accurate in this matter.

But, you will say, how then am I to be certain that the observations, each and every one, have been carried out as skilfully and as correctly as possible? I answer:

[Margin: Quænam circa parallaxium negotium notari debeant.] *What must be noted in the business of parallaxes.*

1. Never, indeed, trust one single observation, even if it was obtained by the most practised observer of all, with any instrument however perfect; much less presume to derive certain very great things from it, or to explore the subtler parallaxes. Rather, procure for yourself many different observations of every day.

[Margin: Non omnes obſervationes calculo parallaxium commodè adhibentur.] *Not all observations are conveniently applied to the calculation of parallaxes.*

2. Continue the observations from day to day, as far as can ever be done, and collect a great number of them; then from among them choose the more accurate ones, and those better suited to the business of parallaxes. For not all observations suit every time, every circumstance and the calculation, even when they have been carried out most correctly. Besides, it is altogether impossible to observe each and every observation always with equal diligence, because of various obstacles.

[Margin: Diverſis inſtrumentis obſervationes peragendæ ſunt] *Observations are to be carried out with various instruments.*

3. Carry out the observations not with one instrument only — whether a quadrant, sextant, octant, radius, armilla or some other instrument, however large — but with instruments of different kinds: now the radius (not that much is to be attributed to it, but for the sake of greater certainty), now the azimuth quadrant, now the sextant, or some other instrument suited to this business. For not all instruments can serve you equally well at once, at any time and place whatever, by reason both of the position of the phenomenon and of the observatory.

[Margin: Diverſa calculi methodus,ſecuriores reddit computatores.] *A varied method of calculation makes calculators more secure.*

4. Do not put your trust entirely in one calculation, nor in one method of computing parallaxes; rest content only at last, once they have been compared and tested by a good many examples and by various routes returning to the same calculation.

With all these things carefully attended to — that is, with observations by instruments of many kinds, with the greatest industry, by a most practised celestial investi- gator, collected into one bundle, the doubtful ones rejected and the more certain kept — and when each and every observation has then been subjected to a more precise calculation and worked out by a varied method, you will clearly perceive that from any observation whatever, drawn from the sky itself with this instrument or that and brought to the same time, the same calculation always comes out. From this you can be certain that no evident error has been committed, either in the observations or in the computations. But if the calculation reveals that the observations waver and fluctuate this way and that, and come out one way with the help of this instrument and another way with that one, you will easily conclude that the observations are doubtful and therefore to be rejected, and that nothing accurate is to be built on them.

[Margin: Quâ ratione omnis evidens error animadvertatur in eruendis paral- laxibus.] *How every evident error is detected in deriving parallaxes.*

For if everything is as it should be, then necessarily, from the quadrant as well as from the sextant or octant, and with every calculation duly made, every result will always be wholly equal to every other, or only a quite negligible small difference will be noted. For it can never at all happen that, in so many observations obtained with the most diverse instruments and worked out by so very diverse a calculation, we have been deceived in one and the same way, so

that the products of the calculation agree entirely, almost in the same minutiae of the seconds. Therefore, if you find in actual fact, as we have just said, that the quantities sought from all the data — taken from any observations whatever and obtained in any way whatever — correspond both to the time and to the motion, by reason of increase as well as of decrease, then certainly full trust is to be placed both in the observations and in the calculation.

[Margin: Autor quâ ratione Cometam infectatus eſt.] *By what method the author pursued the comet.*

In this way, then, we too set about our comet, both to investigate the parallaxes the more accurately and to satisfy all the more the lover of the stars who desires the truth. So from the very first day of the phenomenon's appearance right up to the last, not content with one or two observations of it, I made as many as the circumstances of the time, the clearness of the sky and its face ever allowed me — not only with our azimuth quadrant, very accurately constructed, but also with the sextant, and sometimes even with the radius. I attribute little to the radius, however, in the business of parallaxes, and I did not use those observations where others were at hand. Then, for the sake of greater certainty, and to win the minds of our opponents over to us all the more, I went to seek the parallaxes of the phenomenon itself from those various observations, by the most diverse method, as diligently as could be done.

[Margin: Autor quâ via parallaxes inquiſiverit.] *By what route the author investigated the parallaxes.*

First, from December 23 (for on the 20th it was not yet granted to draw accurate observations from the sky), I investigated them through the distances of the phenomenon from the fixed stars, observed ones where any were granted, and if not, through distances computed in due manner from altitudes and azimuths. Second, through the true and apparent altitudes of the comet. Third, through the true and apparent declinations and latitudes. And fourth, by the method of Regiomontanus. But just as this fourth is the last of all, so the first is certainly the most certain and most accurate of all. Accordingly I also examined the greatest part of the parallaxes by that route, and omitted nothing there that I judged to bear on a more precise and more accurate investigation of them, as the matter itself will show. Moreover, I adopted such methods of calculation — especially concerning the distances of the phenomenon and of the fixed stars lying both near the comet's orbit and at a right angle to the comet and its orbit, and concerning the assumed parallaxes [fictas parallaxes] to be derived from the equated distances [coæquatis diſtantiis], and these to be reduced to the vertical, and also concerning the first and second prosthaphaereses of inclination [proſthaphæreſes inclinationis], to be duly worked out — methods such as, I know very well, no one has used until now, be it said without boasting.

[Margin: Deductis parallaxibus Autoris methodo omninò demonſtrativè ſedes Cometarum exploratur.] *When the parallaxes are derived by the author's method, the seat of comets is investigated wholly demonstratively.*

These methods of computing the true and genuine vertical parallaxes, just as they are applied very fittingly to our comet, so also properly suit the other phenomena; so that by this method we can not only pronounce, as a probability and in Tycho's manner, that comets move above the Moon, but also always argue demonstratively about the true position and seat of comets.

But let us approach the matter itself, beginning by investigating the parallaxes through distances from certain fixed stars, in such a way that first the apparent motion of the phenomenon is duly examined, then its true motion, and lastly the equations and prosthaphaereses. Before we may arrive there, however, I consider it worthwhile to set out clearly each and every thing that must be known beforehand in this business and noted with the greatest care, so that no one fails to understand everything correctly and to penetrate it thoroughly. For this matter is not so easy to grasp and to demonstrate. Indeed, I am not afraid to say that not even those who persuade themselves that they have cultivated astronomy somewhat more deeply will grasp correctly, at the very first glance, everything that pertains here; rather, they too will very greatly need to consider and examine what is to be said with a mind properly intent and not flitting, before they grasp the whole matter perfectly. For this study of parallaxes, above all those of comets, is very nearly the most subtle, most intricate and most difficult of all astronomical matters.

[Margin: Antequam parallaxes aggredimur, opera danda eſt, ut omnia & ſingula rectè intelligantur; cùm res ſit perquàm difficilis.] *Before we approach the parallaxes, care must be taken that each and every thing is correctly understood, since the matter is very difficult.*

[Margin: Autor ſupponit Lectores Scientiæ Aſtronomicæ haud prorsùs ignaros] *The author supposes his readers not altogether ignorant of the science of astronomy.*

Hence, at the outset, before we come down to the particular points to be noted and to the preliminary notions, I suppose that all those readers of this work of mine who are lovers of mathematics already understand what parallax is and of how many kinds, and also have a true knowledge of those general axioms. But since these things are not yet sufficient, we must set out here in advance certain particular axioms and theorems about comets; if these are neglected, the work will be attempted in vain.

[Margin: Theorema parallaxium primum.] *First theorem of parallaxes.*

1. It must be understood that the distance from some fixed star (but taken free of refraction) of any phenomenon lacking all proper motion and parallax — in whatever place in the sky and in whatever position, whether the fixed star is below, or above, or under one and the same vertical as the phenomenon, or removed from the vertical point [puncto verticali] by a space equal to the phenomenon's, or is also inclined in various ways to the equator and the ecliptic — that distance, namely of the phenomenon and the fixed star, is then always of one and the same magnitude at any time whatever. This is quite evident in the intervals of the fixed stars,

whose separation from one another is perpetually the same, provided you measure it accurately.

[Margin: Theorema ſecundum.] *Second theorem.*

2. The distance from a fixed star of a phenomenon that has parallax, even if it is devoid of all proper motion, changes from time to time (even if you remove refraction entirely from both bodies); and it changes more or less in proportion to its greater or lesser altitude above the horizon, and also according to whether the phenomenon is higher or lower than the fixed star, and the line of distance slopes toward the horizon at this or that angle of inclination.

[Margin: Theorema tertium.] *Third theorem.*

3. A phenomenon free from all proper motion but subject to parallax, and placed under one and the same vertical as a fixed star, varies greatly the distance between itself and the fixed star; but very little (if the parallax is small), indeed almost not at all, if the phenomenon and the star are equidistant from the vertical point, or are removed from the horizon by an equal interval; so that the apparent and the true distance are then quite the same.

[Margin: Theorema quartum.] *Fourth theorem.*

4. But if the phenomenon has a proper motion tending upward toward the zenith, and cuts the ecliptic with its orbit at a certain angle, and also possesses parallax, then the observed distances change all the more, the swifter the proper motion is and the higher or lower the phenomenon is with respect to the horizon; whether it stands above or below the fixed star, or inclines to this side or that. And this holds above all if the said distances appear greater and smaller according as the phenomenon is approaching the fixed stars or receding from them.

[Margin: Infallibilis conſequentia.] *An infallible consequence.*

From this it follows that, when a phenomenon has no proper motion but a definite parallax, and stands under one and the same vertical with a lower fixed star, the earlier and lower observed distance is smaller than the other, later and higher one, taken after one or two hours have elapsed, because the earlier parallax is greater and the later one smaller. But with the phenomenon placed below the fixed star, the earlier distance turns out greater and the other smaller, if both bodies are in the eastern quarter and ascending; if, however, the phenomenon and the fixed star are in the western quarter and descending, you will find the contrary. In these cases, therefore, when one distance is subtracted from the other (the altitude of the phenomenon at each observation being known), there remains the difference of parallax of the two given altitudes.

[Margin: Negotium parallaxium longè aliter ſe habet, ſi phænòmenũ, cum motu proprio, ſimul parallaxin poſſid[[e/è]]t.] *The business of parallaxes is quite different if the phenomenon possesses parallax together with proper motion.*

But when the phenomenon exhibits parallax and proper motion at once, this business becomes much more intricate, and then the observed distances

vary in a quite different way — indeed, by reason of the phenomenon's proper motion relative to the fixed star. Hence, if you want the parallax of such a phenomenon, you must necessarily have its proper motion known. When this has been either subtracted from the earlier or the later distance, or added to the other, as the case requires, the difference of the two distances — namely of the one equated and of the other bare — gives the assumed or mean vertical parallax of the phenomenon: that is, if the phenomenon and the fixed star are under the same vertical in one of the two observations, and at the same time the fixed star is very near the orbit, or is found right under it. The matter also comes to the same thing when you take the true proper motion away from the apparent one, or from the difference of the bare distances: the assumed or mean parallax itself results.

[Margin: Quando diſtãtia reducenda ad orbitam & verticalem.] *When the distance is to be reduced to the orbit and to the vertical.*

But when the fixed star is somewhat distant from the orbit of the phenomenon — for example, of ours (for in others the matter can stand one way or another, according to the position of the orbit) — we need a certain equation: namely, by reducing one of the two distances to the orbit, so that the parallax of the orbit results. Indeed, if we look into the matter more deeply, that parallax must in turn be reduced to the vertical, and likewise the prosthaphaeresis of inclination, both the first and the second (about which you will learn more presently), must be applied to it, so that at last the pure and genuine vertical parallax itself, equated a second time, may be drawn out. Otherwise, indeed, it is spurious and adulterated — that is, not purely and simply vertical, but mixed with the parallax of longitude, latitude, declination and right ascension; although sometimes all those equations scarcely run to a few seconds.

[Margin: Quando vicisſim nullâ reductione opus ſit.] *When, in turn, no reduction is needed.*

Furthermore, when the fixed star stands at exactly a right angle to the phenomenon and its orbit, no reduction at all is needed (saving, however, the remaining equations and prosthaphaereses); the proper motion is simply either added to one of the distances or subtracted from it, according as both distances were observed in the same quarter of the sky, east or west, or in different quarters. Unless perhaps the fixed star does not fall precisely at a right angle with respect to the phenomenon and its orbit — as indeed usually happens — but at a certain angle of inclination: then one must likewise use the reduction mentioned above, or the equation to the orbit, though it is to be found by a particular method. This will be treated more fully in connection with the calculation itself, so that I do not, as it were, overwhelm the reader at the outset by delivering too many intricate things at once. So let these remarks suffice, such as they are, which we have just set out in general terms and briefly.

[Margin: Si nullus non hocce negotium parallacticum rectè intelligere debet, adhuc fuſiùs id ipſum pertractandum erit.] *If no one is to fail to understand this parallactic business correctly, it will have to be treated still more fully.*

But perhaps I seem to have dwelt too long on these preliminaries, and to have brought in more than I ought. Yet so far am I, my lover of the stars [mi Aſtrophile], from seeming to have satisfied myself — let alone you, who are perhaps still less practised in astronomical matters — that I rather think a great many things remain to be said, if this parallactic business is to be understood clearly and thoroughly by anyone at all without distinction. For it is not only arduous; cases of many kinds also sometimes arise from the most diverse situations of comets, which can almost overturn the whole matter — as this comet of ours will testify amply and more than enough. Not to mention that, if everything that has been said were to be applied to any phenomena whatever, past as well as future, a separate little book would certainly have to be composed; and neither the time nor our purpose permits that. Nevertheless, so that this matter, for whose sake we took upon ourselves this whole uncommon labour, may be grasped sufficiently and thereby be made clearer and more evident to all, we shall direct everything that follows, as regards both the axioms and the analyses, chiefly to our comet. Moreover, with an accompanying diagram [appoſito Schemate] we shall demonstrate how parallaxes must be exactly derived from the distances of the phenomenon from a fixed star.

[Margin: Quâ ratione ex diſtantiis phænomeni à fixâ, parallaxes erui debeant.] *How parallaxes must be derived from the distances of the phenomenon from a fixed star.*

These, no less than each of the foregoing, can, I believe, be applied fittingly and with great profit to very many other phenomena that exhibit a proper motion.

In the accompanying diagram, let O K P be the horizon, O R P the equator, R Q the ecliptic, F K the meridian; the remaining arcs of circles, descending from F, the point of the zenith, to the horizon, are verticals; G H is the orbit of the comet, A Aldebaran, B the Heel [Calcaneus] or Algol, D Capella, E the Bright Star of Aries [Lucida ♈], C the comet, S Regel. On the left is the configuration of the eastern quadrant of the sky, and on the right that of the western quadrant — that is, the way in which the same stars present themselves to view in each position after a certain lapse of time. But before we proceed with this analysis, it will be useful, for the sake of greater clarity, to set out certain preliminary warnings.

[Margin: Præmonitiones quædam circa parallaxes valde notabiles] *Certain very noteworthy preliminary warnings concerning parallaxes.*

It is therefore to be noted: 1. If you wish to examine parallaxes from distances, you must have at hand two different distances found at different times, whether they were observed with the sextant and the octant, or, from the altitudes, the azimuths and the true time that elapsed between the two observations, the longitudes and latitudes du- ly computed, or whether the apparent distances themselves were afterwards derived from these, it will come to the same thing, provided you have carried everything out accurately and diligently; as will also be manifest from the following examples.

Diagram. An engraved figure in a rectangular plate-mark, uncaptioned, set across the text column between lines 5 and 6 of the page. It is a dome-shaped projection of the sky: the horizon is the curved base, running from P at the left to O at the right, with the foot points I, H, K, L, M and N marked along it, and labelled *Horizon.* on each side. F at the top is the point where the verticals meet; the straight vertical *Meridianus:* ("Meridian") runs from F down to K. The left half shows the eastern configuration (*Oriens*, "East") and the right half the western (*Occidens.*, "West"). In the left half the comet's orbit is a near-vertical line from G at the top down to H on the horizon, labelled *Orbit. Comet.* in its upper part and *Orbit. Com.* in its lower part ("orbit of the comet"); on or beside it stand the star B, *Algol vel Calc.* ("Algol or the Heel"), the comet C, *Cometa C*, drawn as a hatched disc, and the star A, *Palilic.* ("Palilicium"); to its left is the star D, *Capella*, and to its right the star E, *Lucid.* ♈. ("the Bright Star of Aries"); the ecliptic, *Ecliptica.*, runs from the sign of Cancer at the left edge to the sign of Cancer at the meridian; the equator, *Æquator.*, rises from P; the star S, *Regel.*, stands near the foot of the orbit line, beside a further vertical that ends at I. In the right half the orbit runs from H on the meridian up to G at the right edge, labelled *Orbita* and *Cometæ* along it; on it stand the comet C, *Comet*, drawn as a hatched disc, and the star B, *Algol.*; the star A, *Palilio.*, stands on a vertical below the ecliptic; the star E, *Lucid.*, and the star D, *Capella*, stand among the verticals; the ecliptic, *Ecliptica.*, runs from the meridian down to R at the right edge; the equator, *Æquator.*, runs from a point R beside the orbit down to O; verticals from F meet the horizon at L, M and N. Below the frame at the right: *Autor ſculpſit.* ("The author engraved it"). Every label is listed below as read; none is supplied from the text.

- Top: G; F
- Left half: *Orbit. Comet.*; *Meridianus:*; *Algol vel Calc.* B; D *Capella*; *Cometa* C; E *Lucid.* ♈.; *Ecliptica.*; the sign of Cancer (twice: left edge and meridian); *Palilic.* A; *Æquator.*; *Regel.* S; *Oriens*; *Orbit. Com.*; P; *Horizon.*; I; H
- Centre: H (on the meridian, at the foot of the western orbit); K
- Right half: *Capella* D; *Ecliptica.*; *Comet* C; B *Algol.*; G; *Palilio.* A; *Cometæ*; E *Lucid.* [?]; R (beside the orbit); *Orbita*; *Æquator.*; *Occidens.*; R (right edge); O; N; M; L; *Horizon.*
- Below the frame: *Autor ſculpſit.*

[Margin: Ex quibus obſervationibus genuinæ parallaxes verticales [eruantur?].] *From which observations the genuine vertical parallaxes are derived [?].*

Secondly: let both apparent distances of the phenomenon and the fixed star be given either in one and the same quadrant, eastern or western, or the one in the western quadrant and the other in the eastern, or vice versa, if you are endeavouring to elicit parallaxes. From the former case, however, only the difference of parallax of the two altitudes is found, if the comet and the fixed star stand at the same time exactly under the same vertical. Since this, however, seldom happens so precisely, the assumed parallax is here for the most part

reduced to the vertical by a new method devised by us. In the latter case, by contrast — that is, from distances found in different quarters of the sky, the one in the east and the other in the west, or the reverse — the work succeeds far more accurately and more happily. For from these you will learn the genuine vertical parallaxes themselves: above all if you take care to see the comet and the fixed star in the same quadrant and at the same time under one and the same vertical, and in the other, opposite quadrant to observe the line of distance — namely of the comet and the fixed star — roughly parallel to the horizon. Thus from the earlier observation, with the comet and the star placed under the same vertical, you will have a merely apparent distance, in which the parallax itself lies hidden; but from the later one, with the distance parallel to the horizon, you will have the apparent and the true distance at once. For in that position the parallax can by no means appreciably corrupt the distance; in the earlier one, on the contrary, it does so as much as possible. Hence, when one distance is subtracted from the other (but with one of the two first corrected by the true proper motion), the vertical parallax itself will result.

[Margin: De parallaxi fictâ atq; proſthaphæreſi inclinationis.] *On the assumed parallax and the prosthaphaeresis of inclination.*

But if one distance has been found not exactly under the same vertical, and the other not entirely parallel to the horizon — as usually happens — then the assumed parallax, or equal parallax, or parallax of the orbit, is to be reduced to the vertical, and the prosthaphaereses of inclination applied to it, so that the true vertical parallax may become known: as we have already touched on somewhat above, and shall also demonstrate below to the eye.

But let us return to our diagram, from which the matter will become much clearer.

[Margin: Parallaxis diſtantiam à fixâ reddit majorem, ſi fixa altior exiſtat phænomeno, ſub eodem verticali.] *Parallax makes the distance from a fixed star greater, if the fixed star stands higher than the phenomenon under the same vertical.*

Let C B be the earlier distance, of the comet and the Heel — the star very near to the orbit — found in the eastern quadrant, and at a time when both stood roughly under the same vertical, yet in such a way that the fixed star claims the higher place. In this case, therefore, the parallax, if there is any in the observations, depresses the comet toward the horizon according to its nature and magnitude, so that this distance B C is rendered greater, by reason of parallax, than it really would be if the comet lacked all parallax — in accordance with Axiom 3, given above. And hence B C becomes the apparent distance itself, in which the parallax lies wholly hidden. That parallax would easily become known if the true distance, known for the same time, were subtracted from this earlier apparent distance B C.

[Margin: Quâ ratione vera diſtantia inveniatur ac corrigatur.] *How the true distance is found and corrected.*

But by what means that true distance is to be found, and rectified with the help of the true proper motion, we shall now teach.

Now, just as it is necessary that one distance of the comet and the fixed star, C B, be known in the eastern quarter under the same vertical, so also the other — in the western quadrant, roughly parallel to the horizon, that is, when the comet and the fixed star are removed from the vertical point by an equal interval — is required above all.

[Margin: Diſtantia horizonti parallela ſimul viſa & vera eſt.] *The distance parallel to the horizon is apparent and true at once.*

For this latter one, as is clear from the preceding diagram to anyone who considers the matter somewhat more attentively, is at once the apparent and the true distance, and entirely free from all parallax, according to Axiom 3. For that distance — namely when the comet and the fixed star are equidistant from the horizon — is not distorted even in the least, even if some parallax is present: unless perhaps the parallax is very large, namely of several degrees; and even supposing it to be so large, the difference will still scarcely extend to a very few minutes.

[Margin: Quo in loco parallaxis in perceptibilis ſit.] *In what position parallax is imperceptible.*

The reason is this: although the comet in that position is depressed from its true place toward the horizon by reason of parallax just as before, nevertheless, despite that depression, the distance C B (namely in the western quadrant, where the Heel B is removed from the horizon right at the comet's side and equally with the comet) is in no way varied. And even if you were to grant that it varies, the change is still by no means so great that it could be perceived, or that anything could thereby be taken away from the parallax even in the seconds. Indeed, suppose the parallax to be a whole degree, and the distance at the same time to be twenty degrees and more, or even 30: you will still barely, if at all, notice a difference of one minute. From this one may judge how small the difference would be if the parallax amounted to only a few minutes (as can be seen in our comet): it will then surely show us a difference of scarcely one or two seconds.

[Margin: Diſtantia ſub eodem verticali obſervata, viſa tantummodò eſt.] *The distance observed under the same vertical is only apparent.*

Since this is so, the distance parallel to the horizon, as seen, is always also the true one; while the vertical distance, observed under the same vertical, represents only the apparent one, to which the parallax plainly adheres, and in which the parallax, if any is present, is detected as perceptible. Therefore, when the one is simply taken away from the other, there remains the parallax sought itself: provided that the comet is driven by no other motion than the first motion.

[Margin: Diſtantiæ [[;/,]] ratione motus proprii corrumpuntur.] *The distances are corrupted by reason of the proper motion.*

But since our comet possesses a notable proper motion, as was shown at length in the foregoing, that later distance parallel to the horizon is vitiated. Accordingly, this proper motion, accomplished between the two observations,

must be separated from one or the other of the distances, by addition or subtraction according to the phenomenon's approach or recession, so that one or the other distance may become known as true. Then, in turn, take the one away from the other, as we have just said, and you will have the parallax itself.

[Margin: Multùm intereſt cognoſcere, an Cometa, ratione fixæ alicujus, in acceſſu, an verò in receſſu feratur?] *It matters greatly to know whether the comet is moving in approach or in recession with respect to some fixed star.*

In this operation, however, I would have you note above all in which direction the comet holds its own proper course: whether, with respect to the fixed star, it is moving in approach or in recession. And since it is certain that our comet always directed its path upward, toward the zenith, from the Hare [Lepore] through the equator and the ecliptic toward Cassiopeia, the said comet certainly became gradually nearer to the Heel (namely in the first days of its appearance; in the later days the contrary happened), and was in approach, at that time in the eastern quadrant, always lower than the fixed star; and so, as a consequence, that later distance parallel to the horizon was notably diminished in the interval that elapsed between the two observations.

[Margin: Quomodo parallaxis orbitæ innoteſcat.] *How the parallax of the orbit becomes known.*

Therefore the proper motion of the comet that correctly corresponds to the given time elapsed between the two observations, taken from our table often mentioned, inserted in Book I, Section X, page 109 [Lib.I Sect. X pag.109], should be added to the later, parallel distance — or, what is the same thing, taken away from the earlier distance — so that one of the two is reduced and transformed into a true distance with respect to the other, apparent one, just as if the comet had been subject to no proper motion. Afterwards, when the one is taken away from the other — namely the apparent from the true, or vice versa — the parallax of the orbit springs out: on this condition, however, that the fixed star stands either under the comet's orbit itself or very close to it; if not, the said fixed star is first to be reduced. But how this investigation ought to be conducted it is not fitting to say at present, lest I overwhelm the reader's mind with more than a great many most abstruse things, and perhaps draw his attention away from the matter taken up earlier and not yet finished; we reserve it for another time, in connection with the presentation of the calculation itself.

[Margin: Diſtantias ab omni motu proprio liberare.] *To free the distances from all proper motion.*

Besides this way of stripping one or the other distance of all motion, there remains another to be described, which I have used not infrequently. Take one bare distance away from the other bare distance, and the difference will show you the apparent proper motion of the comet — a mean, as it were, or assumed motion, corresponding to that particular time. From this, in turn, subtract the true apparent proper motion of the comet taken from the table for that time, and the genuine parallax sought will result: that is, when there is no need of reduction to the vertical, nor of the prosthaphaereses of inclination. Otherwise

the parallax found is only mean and assumed, and always fits only that altitude — which you should note well — at which the comet stands together with the fixed star under the same vertical; but it by no means fits the other altitude, when the distance was parallel to the horizon, since that distance is almost free, as far as parallax is concerned, of all variation.

[Margin: Quando motus viſus vero major eſt.] *When the apparent motion is greater than the true.*

Moreover, I think it should be pointed out here that, when the comet is moving in approach to the Heel, the apparent motion is always greater than the true one, if there is any parallax in the observations: that is, if the fixed star is found either under the orbit itself, or very near to the orbit and the vertical. But if the fixed star is removed from the orbit and the vertical by a notable space, know that the contrary happens, and the apparent proper motion is smaller than the true one. I shall deal with these matters more fully shortly, and shall set out definite axioms by whose help the whole matter can be settled with the greatest ease. And let this suffice about this method of investigating parallaxes when our comet in particular is moving in approach to a fixed star and at the same time sits near the orbit together with the fixed star.

[Margin: Ratio parallaxes inveſtigandi quando Cometa ad Stellam in receſu verſatur.] *The method of investigating parallaxes when the comet is moving in recession from a star.*

Conversely, when the comet — in the earlier, eastern observation, that is — stands under one and the same vertical as a fixed star, such as Palilicium A or Regel S, or not far from it, and is in recession from the star, namely gradually receding from it, the true proper motion is taken away from the later distance, the one parallel to the horizon, or added to the earlier one. Afterwards the difference of the two distances yields an assumed, or equal, parallax.

[Margin: Regulæ benè notabiles.] *Rules well worth noting.*

In sum: whether the phenomenon is above or below the fixed star, provided it is in approach, the true proper motion is always added to the later distance parallel to the horizon; but in recession it is subtracted from that same later distance. Or vice versa: in approach the true proper motion is taken away from the earlier, vertical distance, and in recession it is added to that same distance. The matter comes to the same thing, as we have already touched on, if the comet is in recession with respect to the fixed star: then the difference of the bare distances, or the apparent proper motion, is likewise always greater than the true proper motion — but only in those cases when the fixed stars from which the distances were taken are seen either under the comet's orbit itself and under the same vertical, or very near to these, or at least not very far from them, namely in the earlier, eastern observation; and when at the same time, in the later, western observation, the fixed star and the comet are at exactly equal distances from the horizon, or the fixed star is a little less — that is, somewhat lower. Then, I say, the apparent proper motion is always greater than the true one. But if the fixed star is higher than the comet, the whole business is

reversed, as will be explained shortly afterwards, once the things that must be set out first have been dealt with.

[Margin: Quando motus proprius viſus vero major eſt.] *When the apparent proper motion is greater than the true.*

But when the fixed star, with the comet receding from it more and more, does not stand exactly under the same vertical (namely in that region of the sky in which this ought rightly to happen) nor near it, but is removed by a fairly large interval, so that the comet and the fixed star must pass through two very different verticals, one each, forming a quite notable angle at the zenith [ad verticem]; and so that likewise the angle formed by the comet's vertical and the line of the distance to the comet is still greater and more obtuse (such an appearance, namely, as Aldebaran presented to us with the comet in the first days of its appearance, and Algol in turn with it in the later days, when the comet was higher than the fixed star and receding): in that case the apparent proper motion is always greater than the true one, if there is any parallax in the observations.

Certainly, hardly everyone will persuade themselves of this, since the matter is very difficult to grasp, and moreover in itself quite hidden and intricate, so that it can hardly be unravelled in a few words. I shall nevertheless labour, as far as I can, to set the matter out and demonstrate it graphically to any attentive reader. For it matters greatly to the attainment of our end that everything be correctly understood, both for other purposes and also for understanding the prosthaphaereses of inclination. Believe me, without knowing these, it is wholly impossible to penetrate the properties of those prosthaphaereses — namely, in what way they are to be applied to parallaxes reduced to the vertical.

[Margin: Quâ ratione proſthaphæreſes parallaxibus ſint applicandæ graphicè declaratur.] *How the prosthaphaereses are to be applied to parallaxes is set out graphically.*

In the following figure let there be the vertical point; A C D S and A B, verticals; B, Aldebaran; C, the comet in the earlier observation; F, the comet in the later observation; the line B D parallel to the horizon; and B C the distance of the comet and Aldebaran. Now we said, in the explanation of the preceding diagram, that when the comet is higher than the fixed star and in recession, and both then stand exactly under the same vertical in the earlier observation — as here the comet C and Regel S — the parallax depresses the comet toward the horizon and makes that earlier distance C S smaller, but makes the apparent motion, between the comet's first station and F, the second, greater.

Diagram. An engraved figure beside the opening lines of the page. Three curved lines descend from A at the top to a curved horizon at the foot: a left arc, a middle arc passing through the star B, and a line passing in turn through F, E, C, D and S; a fourth arc descends from A on the right to the horizon. Straight lines join B to C and B to D; a dotted arc runs from near B up to E, and a dotted line from C down to G. Labels as read on the figure:

- A (top): A

- F (upper middle, on the right-hand line): comet symbol, with "Cometa." *comet* on its left
- E (on the same line, above C): E
- C (on the same line): comet symbol, with "Cometa." *comet* on its right
- B (left of centre, on the middle arc): star, with "Palilit" on its left — so engraved, seven letters; the star the text calls Aldebaran
- G (below the line B D, left of the right-hand line): G
- D (on the right-hand line, at the end of the line from B): D
- S (lower middle, on the right-hand line): star, with "Regel." on its left
- Horizon (lower centre, on the horizon curve): "Horizon." *horizon*
- Below the frame, lower right: "Aut. ſculps." *the author engraved it*

No letter other than A stands at the top of the figure, where the verticals meet, and the text of p. 225 gives the vertical point no letter.

For in recession the earlier distance is smaller than the later one, and besides, that earlier distance is made still smaller than it really is in itself; so certainly, when the one is taken from the other, that difference of the distances, or the apparent motion, becomes greater than the true — namely around those fixed stars that stand under the same vertical as the comet in the earlier observation and are equally removed from the horizon in the later observation. For by the depression of the comet C toward the fixed star S, that distance is diminished.

[Margin: Quando motus viſus, vero minor eſt.] *When the apparent motion is smaller than the true.*

But when the comet and the fixed star are found in the earlier observation under two very different verticals forming a notable angle — such as Aldebaran at B and the comet at C — so that the vertical A C makes a quite obtuse angle with the line of the distance C B (an angle which in the earlier case, under the same vertical, vanished entirely, as is clear from the distance C S of the comet and Regel): in such a configuration, I say, exactly the contrary happens. For although the comet C is truly higher than the fixed star B and the line parallel to the horizon, and on this basis the comet is depressed by reason of parallax toward the fixed star and the line D B parallel to the horizon, the earlier distance does not for that reason always turn out smaller, as happens with Regel S and the comet C under the same vertical; but not infrequently it is even greater.

For if you drop the perpendicular B E from the fixed star B onto the comet's vertical, it necessarily falls, as is known, exactly at a right angle. Hence all the other lines proceeding from the fixed star B to the comet's vertical, whether they are higher or lower than C, are necessarily always greater than the perpendicular B E, according to Euclid, Theorem 21, Proposition 19 [Theor. 21 Prop. 19], and the corollary of Clavius [Christoph Clavius] to the same proposition, where it is demonstrated:

[Margin: Linea perpendicularis omnium breviſſima eſt.] *The perpendicular line is the shortest of all.*

Of all straight lines drawn from any point to any straight line whatever, the one that is perpendicular is the least. From this it follows that, as long as the comet sits

above the perpendicular line B E, so long does the parallax make the distance C B smaller, and consequently, in the said case, the apparent motion greater. But when the comet C stands below the perpendicular line B C (as mostly happened in our calculation, to be appended, around Aldebaran, Algol and the Heel, while the comet was moving in recession), the parallax, by depressing the comet toward the fixed star B and the line B D parallel to the horizon, no longer makes the distance B C smaller, but greater. For all lines falling below the perpendicular continually increase, according to the theorem just cited. Besides, the parallax depresses the comet not along the perpendicular line E G, nor in the same vertical, but in a different vertical A C D, inclined to the line B D, toward D.

[Margin: Regulæ pro parallaxibus.] *Rules for parallaxes.*

Hence, when the comet stands above the fixed star, and both are under one and the same vertical, and the fixed star is under the orbit itself, the apparent motion is indeed always greater than the true; but not always when the comet, though above the fixed star, is moving with each under its own vertical. Rather, the apparent motion is greater than the true only at that time when the comet is found to be also above the perpendicular line B E drawn from the fixed star B to the comet's vertical. But when — note well — the comet already lies on the perpendicular line B E itself, or somewhat below it, the apparent motion, I say, is smaller than the true. This almost always happened in our calculation around Aldebaran, Algol and the Heel, while the comet was in recession; and for this reason the apparent motion was then indeed always smaller, if there was any parallax.

Moreover, it also often happens that the comet in the western region (where the distance is supposed to be equidistant from the horizon) is not removed entirely equally with the fixed star from the zenith point, or from the horizon, nor stands somewhat below it, but is rather raised a little higher; and besides, that it is lower in altitude in this later, parallel observation than in the earlier, vertical one — as in the example of the following investigations, undertaken from the distances of the receding comet from Palilicium, the Heel and Algol. And then — which I would have you note very well — even supposing that you place the fixed star in the earlier, vertical observation, namely in the eastern region, and the comet nearly under the same vertical, indeed under that very vertical, the apparent motion is nevertheless always smaller than the true, if any parallax lies hidden. This is in exactly the contrary way, as we have already mentioned, from when the comet and the fixed star are under the same vertical in the earlier, eastern observation, and in the later, western observation are either equally removed from the horizon, or the comet is a little lower than the fixed star.

The reason is this: in the comet's recession from the fixed star, the apparent motion in this later, western observation — in which the distance is greater than the earlier one — is always altered, and is shown smaller than it would really have been if the comet and the fixed star had been equidistant from the horizon,

or the comet had been placed a little below the fixed star. This is not only because the comet stood above the fixed star in the later, parallel observation, but because in this observation the comet, with respect to itself and to the earlier observation in the eastern quadrant, was much more depressed in altitude.

[Margin: Hocce negotium ut admodum intricatum eſt,ſic maximâ attentione opus habet.] *As this business is very intricate, so it needs the greatest attention.*

But in the comet's approach to the fixed star, even though a higher place is assigned to it in the later, western, parallel observation, the things that have been said are so far from being able to vitiate the apparent motion that I rather think the apparent motion will be smaller when the comet is lower than the fixed star. This, certainly, is extremely difficult to understand, not only in my judgement but perhaps in that of others as well: above all because cases of many kinds occur, and to elucidate each and every one of them sufficiently, and reduce them to definite general axioms, would be too lengthy a business. But if you set the comet and the fixed star under one and the same vertical in the earlier observation, and again at equal distances from the horizon in the later one, everything can be bound by the most certain rules, which will be added at once; although we shall also strive to be able to refer all those cases which our calculation of parallaxes contains to definite classes and axioms. But the axioms of the remaining cases, if any remain, by those who excel in ingenuity and are endowed with keen and refined judg- ment, will, I hope, be constructed without very great difficulty when they need them, provided they direct their minds solely to this matter.

[Margin: Ex quibus certò cognoſcitur phænomeno ineſſe parallaxin] *From which it is known for certain that there is parallax in the phenomenon.*

Meanwhile, keep this for yourself by way of a supplement [mantiſſæ loco]: it makes no difference whether, at the very start of the calculation, you know or do not know whether the apparent motion ought to be greater or smaller than the true, if there is any parallax in the observations. But as soon as you notice that the difference between the distances reduced to the orbit is greater than one or two minutes, presuppose that parallax is present and continue the calculation; provided you rely on more accurate observations, you cannot be deceived. But if you find the difference of the corrected distances to be smaller than one or two minutes, or of only a few seconds, you must look into the matter more deeply. And if you cannot do this, I would have you consider another example, in which the fixed star viewed the comet and its orbit at a right angle. From that, I say, I hope you will be helped not a little, and will at once perceive whether there is any parallax or not. For those cases can be defined far more accurately, and contained and set out in fewer axioms, which will be brought forward in due time.

[Margin: Animadvertenda, quando Fixa Cometam ejusq; orbitam ad angulum normalem adſpicit.] *Points to be noted when the fixed star views the comet and its orbit at a right angle.*

This is roughly what we had to say about the case when the fixed stars from which the distances were taken are placed either under the comet's orbit itself or not far from it. It follows that we should also set out briefly the other business: when the fixed stars are seen at exactly a right angle [ſub normali angulo] to the comet and its orbit. There the matter stands very differently, as can be clearly seen from the earlier figure set beside the text. In it Capella D (as was also done in our observations around the Bright Star of Aries and the bright star of the side of Perseus [Lucidam lateris Perſei]) sits in the eastern quadrant exactly perpendicular to the comet C and its orbit E C G, together with the comet, on a line roughly parallel to the horizon. This distance is to be held entirely as true as well as apparent, since parallax, even if some is present, cannot corrupt it, according to Axiom 3 [Axiom.3.] given above. Again, in the western quadrant the comet C and Capella D acknowledged the same vertical. Therefore the distance taken there is notably vitiated and made greater than it was in itself — namely by depressing the comet toward the horizon and moving the comet perpendicularly away from Capella; and so, as a consequence, this later distance is really the apparent one. When the one is taken from the other, therefore, the mean parallax results, which at other times we also like to call equal, or assumed.

[Margin: De parallaxi mediâ, æquali ſeu fictâ.] *On the mean, equal or assumed parallax.*

And here there is no need to attend to the proper motion; indeed, even if the comet has some motion, it does not hinder this matter at all, unless perhaps it is huge and extremely rapid. For since Capella, or the Bright Star of Aries, occupies a position exactly at a right angle with respect to the comet and its orbit, the proper motion adds very little, indeed almost nothing, to the distances D C or C E, or takes it away — even supposing that the comet moves upward or downward by its proper motion by a few minutes — provided that the distances between the comet and the fixed star are not very small or, what is the same thing, the fixed stars too close to the comet, but that they are removed from each other by at least 15°, 20° and more, as mostly happens in our observations and calculation.

But if the fixed stars — for example Capella or the Bright Star of Aries — not quite exactly at the right angle itself, but only approximately, to the comet and its orbit, are ob- served, where the comet's proper motion — perhaps quite conspicuous at that time, and swift — can harm the parallax not a little, it will be entirely necessary first to reduce and limit the distances by a particular method of calculation devised by me; but we have proposed to treat this separately later, to avoid greater confusion.

[Margin: Axiomata pro diſtinguendo motu viſo à vero; Fixâ ſub ipsâ,vel prope orbitam exiſtente.] *Axioms for distinguishing the apparent motion from the true, when the fixed star lies under the orbit itself or near it.*

From what we have recounted, I think that anyone not altogether unversed in astronomical matters has understood by what reasoning the parallaxes, above

all those of our phenomenon, are drawn out from the distances of the comet and the fixed stars, and what must be attended to most carefully in investigating them; although I have no doubt at all that almost everything can also serve for other phenomena, if it is applied with judgement. So that what has been said at length so far can be grasped the more easily, and also carried over with profit to the practice of calculation, here are some axioms for you, derived from what was said before and extremely necessary. Without them, indeed, even someone by far the most practised is scarcely able to take up this arduous and intricate business without faltering, let alone distinguish accurately at all times whether parallax attaches to the given observations and distances or not. The greater the labour with which we have constructed these axioms, the less you will need to grasp each point with their help — especially the points worth noting about the apparent and the true proper motion; and also by what method, and at what time, the distances between the comet and the fixed star are diminished and increased relative to each other, if there is any parallax. But this is only for the position, as we have already warned rather often, in which the fixed star is placed under the orbit itself or near it; the other situation, at a right angle, will be dealt with later.

Axioms of parallaxes, with respect to the true and apparent motion, when in the earlier, vertical observation the comet and the fixed star stand either under one and the same vertical or under different ones — the star, however, lying under the orbit or not very far from it — and in the later observation, parallel to the horizon, the comet and the fixed star are entirely equidistant from the zenith point [Axiomata parallaxium, ratione veri & viſi motus, Cometâ & Fixâ in priore obſervatione verticali, ſive ſub uno eodemq; verticali, ſive diverſis exiſtentibus; Stellâ tamen ſub orbitâ, vel non adeò procul ab eâ degente : in poſteriori verò horizonti parallelâ obſervatione à puncto Zenith, Cometâ & Fixâ omninò æquidiſtantibus.]

[Margin: Axioma primum.] *First axiom.*

1. When the comet, in the earlier, vertical observation, stands below the fixed star and in approach to it, whether under the same vertical or under different verticals — the star, however, lying not far from the orbit — and in the later, parallel observation the comet is removed from the horizon equally with the fixed star, or a little above the fixed star, the apparent motion is always greater than the true, if any parallax is present. And this comes out greater or smaller according to the smaller or greater altitude of the phenomenon,

[Margin: Axioma ſecundum.] *Second axiom.*

2. Given that the comet, in the first, vertical observation, is below or above the fixed star, but below the perpendicular drawn from the fixed star to the comet's vertical, and in recession from the fixed star — whether they are found under the same vertical or under different verticals — and that in the later, parallel observation the comet and the fixed star are equally distant from the horizon, or from the zenith point, then the

difference of the distances, or the apparent motion, is always smaller than the true, if some parallax lies hidden. But with the comet placed, in the earlier observation, above the fixed star and the perpendicular, likewise in recession, the apparent motion is greater than the true.

[Margin: Axioma tertium.] *Third axiom.*

3. When the comet, in the earlier, vertical observation, is under the same vertical circle as the fixed star, or under different ones, and is observed both above the fixed star and the perpendicular line and in approach; and again, in the later, parallel observation, the comet and the fixed star are removed from the horizon by an equal interval, the apparent motion is smaller than the true. But if they are found under different verticals, and the comet is then below the perpendicular line, even though it appears above the fixed star, the apparent motion is greater than the true, if any parallax attaches.

[Margin: Axioma quartum.] *Fourth axiom.*

4. But when the comet is in recession, and in the first, vertical observation is with the fixed star either under the same vertical or under different ones, yet above the fixed star and that perpendicular line so often mentioned; and in the second, parallel observation both are equally removed from the horizon — and no differently when the comet is a little lower than the star — the apparent motion, or the difference of the distances, is likewise greater than the true. But the contrary happens if the phenomena are found under different verticals and the comet below that perpendicular line, even though it seems to be above the fixed star; and if in turn, in the later, parallel observation, either the comet and the fixed star are entirely equidistant from the horizon or the comet stands a little lower, the apparent motion is smaller than the true, if any parallax is present.

[Margin: Axioma quintum.] *Fifth axiom.*

5. If the comet, under different verticals, is found in the earlier, vertical observation above the fixed star and in recession, even though it is also much higher than the perpendicular; and in the later, parallel observation the comet is higher than the fixed star and the perpendicular, the apparent motion is smaller than the true, if there is any parallax.

And so it stands with the apparent and the true motion when — which you should note very well — the earlier observed distance was vertical and the later one parallel to the horizon. But when the contrary occurs, namely that the earlier observed distance is parallel to the horizon and the later one vertical, everything that has been said is to be taken in the contrary way.

[Margin: Motum Cometæ proprium rectè traditum esſe.] *That the comet's proper motion has been correctly set out.*

But, you will say: I do not doubt that everything really stands so, just as it is also excellently founded in the truth of the matter, so that nothing whatever can be brought against it by anyone with reason — provided, that is, that you have the comet's proper motion known very accurately. But how is it to be

investigated, and from where may I be certain that it is entirely true? I answer: this true proper motion of the comet is to be taken, with due proportion made, from our later table of the proper motion, set out for the single days and hours of the comet's whole apparition and inserted in Book I, Section IX, page 110 [Libr.I. Sect.IX.pag.110]. That the proper motion has been set out most correctly in that table I forbear to demonstrate here at greater length, to spare time and paper, referring those in doubt to Sections IX and X of Book I. There we sought that motion very scrupulously and anxiously from a good many observations by means of lengthy calculation, and we handled the business as circumspectly as could ever be done, just as it would have had to be attempted for the other planets too, if their motion had not yet been explored. So I am entirely sure that no one can find anything wanting in this respect, unless someone wishes to bark against sound reason altogether and to deny our principles completely. Against such a person, indeed, I think there should be no disputing; he is to be left to his own opinion, to enjoy it alone.

[Margin: Non promiſcuè omnes obſervationes ad parallacticum negotium adhibendæ[[./:]]] *Not all observations indiscriminately are to be applied to the parallactic business.*

Finally, before we come to the calculation itself, I consider it of the utmost importance to warn in advance that not just any observations can be applied to this parallactic business, but only those acquired with singular diligence: those in which the distances were found to be neither too small nor large; in which the altitudes were neither too near the meridian, nor the azimuths too far removed from it, etc. The limits of time do not permit us to list them all. If these are supposed otherwise, misshapen and utterly monstrous triangles are supplied, so that scarcely anything accurate can be computed from triangles of that kind. And, to say it in three words, whoever strives to undertake this labour must not only be much practised in the astronomical dust, and well acquainted with all matters and capable in them; it is also necessary that he be endowed with excellent judgement, so that he is not unable to weigh each point duly and examine it exactly — above all, to separate the truer from the doubtful — and that he know best with what things, and with what kind of calculation, these or those observations agree, and also what should be done and what not. For not everything suits everyone, or every time, fittingly. For even if some thing is useful and excellent in itself and with respect to some definite matter, yet with respect to another matter it could be quite useless and very bad.

[Margin: Quasnam obſervationes Autor uſurpaverit.] *Which observations the author used.*

Hence it also happened that we were not permitted to compute parallaxes from just any observations, but only from those that served our purpose. Such were, above all, those made on the same day, or repeated within the space of twenty-four hours, and at the same time in the eastern and the western quadrant: namely, with the comet and the fixed star given under one and

the same vertical in the one observation, and with the distance parallel to the horizon in the other.

[Margin: Calculus parallaxium admodum operoſus.] *The calculation of parallaxes is very laborious.*

From whatever suitable observations there were, therefore, we went on to seek parallaxes, shirking none of the labours, however disagreeable and harsh, that had to be undertaken to track them down. Moreover, I was very rarely content to set up and carry through the investigation of any calculation by one single method; mostly I used very different ones, so that everything might be computed, examined and presented duly and correctly. And I believe — if the word may be pardoned — that we have omitted nothing that I ever judged would contribute even the least to that calculation, as all fairer critics of our works will candidly admit.

[Margin: Quare ex obſervatione diei 20 Decemb. parallaxis erui haud poſſit.] *Why the parallax cannot be derived from the observation of December 20.*

Let us now approach the calculation itself, since we have prepared for ourselves an easier access for undertaking it. I would indeed wish to begin from the first day of the apparition, namely December 20, and so to be able to derive the parallaxes in the order of all the following days. But since on that first day, the 20th, apart from that single observation drawn from the equilateral triangle, no other sufficient ones were granted, and nothing certain in this respect can be drawn from that single one alone, we must of necessity pass over that day and turn at once to December 23, on which the comet shone for us a second time. Indeed, on this day, the 23rd, we had no observations in which one distance of the comet and of a fixed star lying near the orbit was observed with the sextant under the same vertical, and the other, after some hours had passed, roughly parallel to the horizon. Hence it will be more laborious to undertake the calculations through distances, from the apparent longitudes and latitudes acquired through altitudes and azimuths and entered in the table in Book I, Section VIII, page 86 [Lib. I. Sect. VIII pag.86], which must first be sought out, than through bare distances observed with the sextant. However that may be, let us nonetheless undertake this work eagerly and fearlessly.

The earlier observation, which is to serve the first investigation, was obtained on the 23rd at $7^{h}\ 22^{m}\ 7^{s}$ in the evening, with the comet and the Heel of Perseus lying nearly under the same vertical; the later one at $10^{h}\ 57^{m}\ 20^{s}$ in the evening, with both phenomena equidistant from the horizon — nearly, I say. For this reason the parallax arising from these observations must first be reduced to the vertical, and then the prosthaphaeresis of inclination must likewise be applied to it, so that the genuine vertical parallax may come out. But because the Heel, although fairly near the orbit, was nevertheless not exactly under it, the two distances to be investigated will first have to be corrected and limited by a particular, suitable method first devised by us.

[Margin: Cur integer calculus in quibusvis ſupputationibus annexus fuerit.] *Why the whole calculation has been attached to each of the computations.*

So as not to be too lengthy, however, let us pass over the method of finding the distances, referring everyone to Book I, Section V [Sect. V. Libri Primi], and content ourselves only with the diagram itself and the whole calculation set beside it — which we have likewise resolved to do in all the following computations — so that everyone may the more readily survey the course of the whole calculation and weigh all the numbers rigorously.

Diagram. An engraved figure in a rectangular frame at the left of the measure. A horizontal straight line near the foot is the ecliptic; great-circle arcs descend from the point A at the top of the frame and cut the ecliptic at B, C and G; straight lines run from the star E down to the comet at L (with M) and at I. A straight line, the comet's orbit, runs from the upper right down to the left through F and H to the comet at I. Dotted lines run from E to D, to K and to F, and from E down to the ecliptic near H; a dotted arc joins M and L. Labels as read on the figure:

- A (top, apex of the arcs): A
- A (upper right, a second, larger italic letter standing apart from the lines): A
- D (left, on the outer arc): D
- K (left, below D): K
- Calcan. (above the star E): "Calcan." — the Heel
- E (right of the star): E
- F (on the orbit line, right): F
- Cometæ (along the orbit line, above F): "Cometæ" — of the comet
- Orbita (along the orbit line, below F): "Orbita" — orbit; with the label above, "Orbita Cometæ", the comet's orbit
- B (below the ecliptic, left): B
- C (below the ecliptic): C
- H (below the ecliptic, at the orbit): H
- G (below the ecliptic, right): G
- Ecliptica. (right end of the ecliptic): "Ecliptica." — ecliptic
- M (left of the comet at L): M
- L (right of the small circle): L
- Comet. (beside L): "Comet." — comet
- I (right of the small circle at the foot): I
- Comet. (beside I): "Comet." — comet
- Aut. ſculps. (lower right): "Aut. ſculps." — the author engraved it

No label on the figure was left unread. The text of this page names A, B, C, E, G, H, I and L; D, K, F and M stand on the figure and are not named in the text of this page.

[Margin: Elucidatio Schematis & analyſis Calculi.] *Explanation of the diagram and analysis of the calculation.*

In this figure, therefore, and also in all the others of this kind — let this be said once for always, both to save time and so that we do not sicken the reader with cabbage reheated so often — let G H B be the ecliptic, A its pole, I the

place of the comet at the earlier observation, and B its longitude, I B its latitude; L the place of the comet at the later observation, C its longitude, C L its latitude; E the Heel of Perseus, G its longitude, and E G its latitude. First, from the angle G A B — namely the difference of the longitudes of the Heel and of the comet at the earlier observation — and from the sides A I and A E, the latter being the complement of the latitude and the former made up of the latitude and 90°, the distance E I of the comet and the Heel at the earlier observation is sought, namely at $7^h\ 22^m\ 7^s$ in the evening. Then by the same method, from the angle G A C and the sides A E, the complement of the latitude of the Heel, and A L, the distance of the comet from the vertical point, let the distance E L itself of the later observation be found, at $10^h\ 57^m\ 20^s$ in the evening.

Investigation of Parallax I, for December 23, from two altitudes of the comet taken with the large azimuthal quadrant [Inveſtigatio Parallaxeos I. ad diem 23 Decembris ex duabus altitudinibus Cometæ,Quadrante magno Azimuthali captis.]

But the true motion, from our table, for $3^h\ 35^m\ 13^s$ is found to be			1° 4′ 34″		
The difference of the apparent and the true motion gives the mean parallax			10 3		

246

[Margin: Parallaxin ſubeſſe præſumitur.] *A parallax is presumed to be present.*

Once the two distances have been found in this way, let one be subtracted from the other, and the apparent motion of the comet results. Since this is

[245] the page sets this calculation as unruled lines, italic labels with roman figures and point-letters, with short rules under the figures of the fourth, eighth, eleventh, thirteenth and fifteenth lines. The table follows the page's order of groups along each line; its blank header row is not printed. Most degree, minute and second figures stand bare on the page; the marks are supplied here in the house form. The tags *A.* (after the latitude), *Add.* and *Subt.* are the page's own; *A.* is not expanded on the page. ♉ is the page's sign of Taurus.

[246] as above, with short rules under the figures of the second, fifth, sixth, eighth, tenth, twelfth and fourteenth lines; the lines from "Antilog. AK" to "Antilog. of the distance EL" stand indented toward the middle of the page. The tags *Add.*, *S.* and *A.* after the logarithms are the page's own and are not expanded on the page; "south" renders the page's *Auſtr.* The last line prints its two figures bare, "10 3", with no marks; they are left bare here. By the subtraction the page prints, the remainder of 1° 14′ 37″ less 1° 4′ 34″ is 10′ 3″.

greater than the true motion taken from our table in Book I, Section X, page 109 [Lib. I Sect. X pag.109] — the motion corresponding, that is, to the time elapsed between the two observations — and since at the same time the comet stands below the fixed star and is approaching it, it is presumed with certainty, according to our first axiom, that a parallax is indeed present in this calculation. Therefore, when the true motion is subtracted from the apparent, there results the fictitious or mean parallax for $7^{h}\ 22^{m}\ 7^{s}$ in the evening — that is, for the vertical observation made in the eastern quadrant, with the comet at an altitude of 44° 28′ — if, that is, the Heel of Perseus had lain exactly under the orbit itself.

But since the aforenamed Heel stood off from the comet's orbit itself by a whole degree and more, the difference of the distances, or the apparent motion of the comet, therefore came out somewhat smaller than if the Heel had appeared under the orbit itself. For this apparent motion is not taken along the same line as the true motion itself: the latter is considered in the orbit itself, whereas the former (namely when the fixed star declines from the orbit) is considered and estimated in a line inclined to the orbit, according to the distance of the fixed star.

[Margin: Id quod motu recto agitur,velocius eſt,quàm quod motu fertur obliquo.] *What is driven with a straight motion is swifter than what is carried with an oblique motion.*

But every body that is driven straight, or recedes from a terminus, is carried forward much more quickly, and approaches the terminus, than one that is drawn with an oblique motion along a transverse line, even if it is endowed with an entirely equal motion. From this it follows that the apparent motion of the comet — estimated, as it is in this position of the comet relative to the Heel, along a transverse or oblique line, namely that of the distance — is necessarily somewhat smaller than if it were taken to be considered in the orbit itself; and also that the straight motion is swifter than the oblique, as will shortly be demonstrated more clearly from the preceding figure.

In that figure, as you have gathered, I is the place of the comet at the earlier observation and L at the later; and so L I is the proper and true motion of the comet in the orbit, and I M the difference of the distances E I and E L, or the apparent motion. Now, therefore, when a perpendicular is let fall from M to L, the hypotenuse L I in that smaller triangle I M L, right-angled at M — namely the true proper motion in the orbit — is certainly greater than I M, the base of the triangle, by Theorem 33, Proposition 47 of Book I of Euclid [Theor. 33. prop. 47 Lib.I Euclid.]. Just so, L I also has a greater ratio to I F than L I has to I E, the hypotenuse, which is greater than the base I F. For the same magnitude has a greater ratio to a smaller magnitude than to a greater, by Theorem 8, Proposition 8 of Book V of Euclid [Theor. 8. Prop.8. V. Euclidis]. For example:

Let the base F I in the right-angled triangle I F E be 24, F E 10, and the hypotenuse E I 26, and L I 2. I say that 2 to 24, counted in the orbit, has a greater proportion than 2 to 26. For 2 to 24 is a 1/12 part of E F, of the

orbit, whereas 2 to 26, the line E I, the distance, is only a 1/13 part of that line. And who does not know that a 1/12 part is greater than a 1/13 part, so that no demonstration is needed?

[Margin: Quò Fixa ab orbitâ magis removetur, eò magis etiam verus à viſo loco differt.] *The farther the fixed star is removed from the orbit, the more the true place also differs from the apparent.*

It follows from this that the farther the fixed star stands from the orbit of the comet, the greater is the difference between the true proper motion L I and the apparent motion I M; that is, the more the fixed star is elongated from the orbit, the more the true motion exceeds the apparent. For the greater the distance E F of the star from the orbit, the greater also is the angle F I E, or L I M. And now, the greater E F is, or that angle which E F subtends, the greater too, certainly, is the hypotenuse E I relative to F I in the triangle E F I, or the hypotenuse L I relative to M I in the triangle L M I. And so, according to the same Theorem 8, Proposition 8 of Book V of Euclid cited above [8, Prop. 8, V Euclid.], the greater the hypotenuse, the smaller is the ratio of the apparent motion I M to the true motion L I.

[Margin: Quo in caſu differentia veri & viſi motus omnium ſit maxima.] *In which case the difference of the true and the apparent motion is the greatest of all.*

But the hypotenuse is greatest of all where the angle F I E, or L I M, is a right angle. Therefore in such a case the difference of the true and the apparent motion is the greatest of all. For there the apparent motion of the comet vanishes entirely, and the difference between the two distances of the comet and the fixed star becomes less than nothing — which was to be demonstrated.

[Margin: Quomodo motus viſus, diverſâ ab autore nunc primùm inventâ ratione limitandus ſit.] *How the apparent motion is to be limited by a different method now first devised by the author.*

Since, therefore, in this first example of parallax the Heel of Perseus is removed a little from the orbit — or, so to speak, has a latitude with respect to the orbit — and for this reason the apparent motion comes out smaller than it actually was, according to the clear demonstration above, reason absolutely demands that this motion be limited. Moreover, accomplishing this very fittingly, in a threefold, indeed a fourfold, way — one handed down by no one before, as far as I know, but devised by me — will be pos- sible. Before I begin to set out these ways, the order of the calculation demands that we first investigate the distance, or latitude, of the Heel from the orbit, E F. And this you will easily obtain by means of its longitude G and its latitude E G, to be taken from the table in Book I, Section III, page 19 [Lib.I, Sect.III. pag.19], and of the point of intersection of the orbit and the ecliptic, H, and likewise the true angle of the orbit and the ecliptic, G H F. These are always to be had from the small table in Section X of Book I, page 111 [Sect. X. Lib. I. pag.111], or more accurately still from the small table inserted in Section XI of the same Book, page 128 [Sect. XI. ejuſdem Lib. pag. 128], with due proportion, however, taken for the given time.

[Margin: Methodus Calculi.] *Method of the calculation.*

1. In the right-angled triangle E G H, let E H be sought from G H, the difference of the longitudes of the Heel and of the point of intersection of the orbit and the ecliptic, and from E G, the latitude of the Heel: that is, by adding their antilogarithms you will have the antilogarithm of the quantity sought.
2. In the same triangle let the angle G H E be sought likewise; you will find it from the logarithms, namely by subtracting the hypotenuse H E from the latitude E G.
3. From the angle G H E thus found, in this case (for sometimes it is also added), subtract the angle of the orbit and the ecliptic; the remainder will be the angle E H F.
4. In the right-angled triangle H F E, from the sum, taken as a logarithm, of the logarithms of the hypotenuse H E and of the angle E H F, there will come out the distance E F itself of the Heel from the orbit, corresponding to the given time. For this distance varies from day to day with the variation of the point of intersection and of the angle of the orbit and the ecliptic; hence that distance of the Heel can by no means serve for the observations of all the days of the comet's apparition, or for every calculation of parallaxes — which we wished to point out at the same time in this place.

Longitude of the Heel	56° 17′ 12″	AG		
Point of intersection of the orbit and the ecliptic	58° 32′ 30″	H	with due proportion taken

[Margin: Quadruplici modò diſtantiæ corrigi poſſunt.] *The distances can be corrected in four ways.*

With the distance of the Heel from the comet's orbit found in this way, let us turn to correcting the difference of the distances, or the apparent motion — or else to limiting the distances of the comet and the star. This can be done, as we have already indicated, in four ways, and it will be no trouble to set out and add them all for the benefit of curious philo-mathematicians.

[Margin: Prior modus.] *The first way.*

1. According to the first way, let both the angle F I E of the earlier observation and the angle F L E of the later observation be sought by subtracting the logarithm of the hypotenuse from the logarithm of the distance of the Heel from the orbit.

2 Since the comet, by advancing, has increased the angle F L E of the later observation (though only very slightly, so that without any loss this operation, even with a still greater given distance of the fixed star from the orbit, could have been neglected), let these two angles be added and the sum halved, so that the corrected angle may come out.

3 In this smaller triangle L I M, let the hypotenuse L I — namely the apparent motion corrected, or limited — be investigated from I M, the difference of the distances, or the apparent motion, and from the corrected angle just found: by adding cossically the mesologarithm of the side to the antilogarithm of the angle (that is, subtracting), so that the mesologarithm of the apparent motion sought results. From this let the true proper motion, found earlier from our table, be taken away; there remains the parallax of the orbit, for the same altitude of the comet, 44° 28′.

Logar. of the hypotenuse EI, distance of the Heel and the comet	15° 22′ 0″	132804

Mesolog. of the hypotenuse LI, or of the corrected apparent motion		382656	1° 14′ 53″
But the true motion from the table is found to be			1° 4′ 34″ *S.*
Therefore the parallax of the orbit for the 23rd, with the comet's altitude 44° 28′			10 19

248

This parallax of the orbit, since the fixed star does not stand exactly under the orbit itself, exceeds the earlier mean parallax by 16″. And that the matter really is so has also been demonstrated at length above.

[Margin: Secunda ratio limitandi diſtantias.] *A second method of limiting the distances.*

But let us carry out this correction and limitation of the parallax by another route, by reducing both distances, I E and L E, to the orbit of the comet. That is, from I E, the distance of the earlier observation, and the angle I E F found above, let the base F I of the right-angled triangle I F E be found; and at the same time the side F L of the triangle L F E, from the distance L E of the later observation and the angle F L E, likewise known: by adding cossically, if need be, the antilogarithm of the angle to the logarithm of the hypotenuse, you will have the mesologarithm of the side sought. I F and L F, once found, give the distances reduced and corrected, and their difference gives the apparent motion reduced and corrected. From this take away the true proper motion given by the table, and there results, as before, the same parallax of the orbit.

Mesolog. of the distance of the star and the comet, EI	15° 22′ 0″	129164 +	
Antilog. of the angle FIE	4° 35′ 39″	322 — *Add.*	
Mesolog. of the distance reduced to the orbit		129486 IF	15° 19′ 11″
Mesolog. of the distance LE	14° 7′ 23″	137986 +	
Antilog. of the angle FLE	4° 59′ 25″	380 —	
Mesolog. of the distance reduced to the orbit		138366 LF	14° 4′ 18″
The difference gives the apparent motion reduced			1° 14′ 53″
But the true motion from the table			1° 4′ 34″
The remainder is the parallax of the orbit			10 19

[248] the page sets this calculation as unruled lines, italic labels with roman figures and point-letters, with short rules under the figures of the second, fifth, sixth, tenth and twelfth lines. The columns follow the page's alignment, and the blank header row is not printed. Most degree, minute and second figures stand bare on the page; the marks are supplied here in the house form, except in the last line, whose two figures "10 19" the page prints bare and which are left bare. The marks + and —, and the tags *Subt.*, *Add.* and *S.*, are the page's own; *S.* is not expanded on the page.

249

[Margin: Quàm præciſè parallaxis orbitæ priori inventæ reſpondeat.] *How precisely the parallax of the orbit agrees with the one found before.*

You see, therefore, that although this inquiry was carried out with the help of a far smaller triangle, and also of both angles found, the parallax of the orbit itself is nonetheless entirely equal to the earlier one, so that not even a single second is lacking.

[Margin: Tertia ratio prioribus præferenda.] *A third method, to be preferred to the earlier ones.*

Yet I shall also disclose a third method of reducing parallaxes to the orbit, which I prefer to the earlier ones. For it is the easiest of all, and here you need no angle: immediately after the distance of the fixed star from the orbit has been found, the matter can be carried out simply from two sides, by solving a single right-angled triangle. I have also always used this method when the given fixed stars were not so very far distant from the orbit. 1 From the hypotenuse E I, the distance of the earlier observation, and the side E F, the distance of the fixed star from the orbit, find the side I F; then, from the hypotenuse E L, the distance of the comet and the fixed star in the later observation, find the side F L in the orbit, by simple subtraction: namely by taking the antilogarithm of F E, the distance from the orbit, away from the antilogarithm of the distances of the comet and the fixed star. Afterwards the difference of the sides found — or of the distances corrected, or reduced — shows the true parallax of the orbit itself.

Antilog. of the hypotenuse IE	15° 22′ 0″	3640.498	to a radius of 8 figures

Antilog. of the hypotenuse LE	14° 7′ 23″	3069.232	
Antil. of the distance from the orbit, FE	1° 12′ 58″	22.528 *S.*	
Antil. of the reduced distance LF		3046.704	14° 4′ 17″
Difference of the reduced distances, or the corrected apparent motion			1° 14′ 53″
The true proper motion is given by the table			1° 4′ 34″
The true and corrected parallax of the orbit			10 19

[249] as above, with short rules under the figures of the second and fifth lines and under the figures 14° 4′ 18″ and 1° 4′ 34″. The marks + and — and the tag *Add.* are the page's own. The last line prints its two figures "10 19" bare; they are left bare.

250

[Margin: Juxta hanc quoq; Methodum eadem parallaxis orbitæ in ipſis ſecundis elicitur.] *By this method too the same parallax of the orbit is obtained, to the very seconds.*

It is clear, therefore, that by this way too, though entirely different and shorter, the parallax of the orbit can be found in exactly the same seconds. However, although this equation and limitation can hardly in any way be made more accurate by us, since, as you see, it agrees with the two preceding ones in the seconds themselves, I shall nevertheless add yet another method of equation, hitherto unknown.

[Margin: Quarta ratio, quando fixæ aliquantò longiùs ab orbitâ phænomeni diſtant, vel ſub angulo normali exiſtunt, admodùm conveniens.] *A fourth method, very convenient when the fixed stars stand somewhat farther from the orbit of the phenomenon, or lie at a right angle.*

I have found it very convenient not only in those cases — namely with fixed stars not very far removed from the orbit — but especially when the fixed stars whose distances were taken are either far removed from the orbit or view the comet and its orbit fully at a right angle. For this reason I have also always followed this procedure afterwards in similar examples.

The distances, moreover, are corrected in such a way, and the matter is brought to such a point, as if the phenomenon had lacked all proper motion; so that there is no need at all to take the true motion away from the difference of the distances — that is, from the apparent motion — or this from that, as has been done until now. Instead, simply by subtracting one corrected distance from the other, bare one, or vice versa, as the case requires, the true parallax of the orbit springs out at once.

[Margin: Analyſis Calculi.] *Analysis of the calculation.*

This operation, moreover, is likewise carried out with the help of the preceding diagram. 1. In the smaller right-angled triangle I M L, let the perpendicular L M be sought: namely from L I, the true proper motion between the two distances of the comet, given by the table, and from the angle F I E, or L I M, already found above. 2. In the same trian- gle, from L I and the perpendicular L M just found, let the side I M be sought. When this is afterwards taken away from E I, the distance of the comet and the fixed star in the earlier observation, it leaves E M in the other right-angled triangle, E M L. 3. And lastly, from the side E M just found and the perpendicular L M, let the distance E L be

[250] the page sets this calculation as unruled lines, italic labels with roman figures and point-letters, with short rules under the figures of the second and fifth lines and under the figures 14° 4′ 17″ and 1° 4′ 34″. The columns follow the page's alignment, and the blank header row is not printed. Most degree, minute and second figures stand bare on the page; the marks are supplied here in the house form, except in the last line, whose two figures "10 19" the page prints bare, the 10 under the minutes and the 19 under the seconds of the line above, and which are left bare. The tag *S.* is the page's own and is not expanded on the page.

computed, which is in reality the earlier distance E I reduced and equated — just as if the comet had had no proper motion. Therefore, when this limited distance is subtracted from the later, bare distance, there remains the parallax of the orbit itself that was sought. How the calculation is to be undertaken by logarithms, however, there is no call to say here, since the procedure of such a calculation already occurs many times in Book I. So the example itself follows.

Log. of the proper motion from the table	LI	1° 4′ 34″	397494

Antilogarithm	LM		0.113 *A.*	
Antilog. of LE, or EI reduced and corrected			3144.838	14° 17′ 39″
But the later distance was found to be				14° 7′ 23″
Therefore the corrected parallax of the orbit				10 16

251

[Margin: Calculorum ſumma convenientia.] *The calculations agree in the highest degree.*

It differs from the parallax found before by only 3″, which is of no consequence at all. I am indeed surprised that, although it was investigated in such diverse ways and at such length, it does not depart further from the earlier one. One therefore argues rightly that this parallax of the orbit, found in four ways for the comet's altitude of 44° 28′, is altogether most true.

[Margin: Parallaxis orbitæ & verticalis differentia.] *The difference between the parallax of the orbit and the vertical parallax.*

But note, as we have already touched on, that this parallax of the orbit is not wholly vertical, but mixed from the parallax of longitude and that of latitude; for that reason it came out somewhat smaller than it was in reality. For in the later distance, with the Heel, the comet was not entirely equally removed from the horizon, but appeared a little lower than the Heel. Therefore, if we weigh the matter carefully, the parallax pressed the comet down a little with

[251] the page sets this calculation as unruled lines, italic labels with roman figures and point-letters, with short rules under the figures of the second, fifth, seventh, tenth and twelfth lines. The columns follow the page's alignment, and the blank header row is not printed. Most degree, minute and second figures stand bare on the page; the marks are supplied here in the house form; the figures "5 10" of the fifth line stand under the minutes and seconds of the line above. The last line's two figures "10 16" the page prints bare, the 10 under the minutes and the 16 under the seconds of the line above, and they are left bare. The tag *A.* is the page's own and is not expanded on the page.

respect to the fixed star, since it then stood in a lower place, and made that distance somewhat greater than it was in itself. Strictly and accurately speaking, therefore, the parallax too ought deservedly to have been greater, however little. How far that small difference extended, however, and how great the genuine vertical parallax itself was altogether, the following calculation will show.

[Margin: De proſthaphæreſi & æquatione parallaxeos.] *On the prosthaphaeresis and equation of the parallax.*

Just as in the western quadrant, in the later, parallel observation, some prosthaphaeresis belongs to the parallax, so likewise in the eastern quadrant, in the vertical observation, a certain further equation is needed. For since in this earlier observation the comet and the Heel did not stand exactly under the same vertical, the parallax of the orbit that was found must by all means be reduced to the vertical; and in this way the said parallax will be made somewhat greater.

[Margin: Reductio ad verticalem parallaxin auget.] *Reduction to the vertical increases the parallax.*

For every reduction to the vertical always increases the parallax. In the western, parallel observation, however, from the prosthaphaeresis of inclination, not always is the parallax made greater, but sometimes also smaller, according to the position of the comet relative to the fixed star. In this first example, which we have in hand, the parallax likewise grows from the prosthaphaeresis of inclination, because the comet and the Heel are not entirely equally removed from the horizon. The chief reason is this. Since, as we have said, the later distance was made a little greater because of the comet's depression, that distance was certainly smaller in itself. Now when you subtract the smaller later distance from the greater eastern vertical distance (as always happens with comets approaching a fixed star), the apparent motion, or the difference of the distances, necessarily becomes greater than if the later distance were set somewhat larger. Given a greater apparent motion, therefore, the parallax too must be greater: for in this case the apparent motion is always greater than the true one when parallax is present — as is clearly seen from the globe and the diagram, if everything is rightly weighed.

[Margin: Non leviuſculus labor parallaxin ad verticalem redigere, & proſthaphæreſes inclinationis indagare.] *No slight labour, to reduce the parallax to the vertical and to track down the prosthaphaereses of inclination.*

Meanwhile, however, to reduce the parallax of the orbit to the vertical in the eastern quadrant, as well as to derive the prosthaphaereses of inclination in the western quadrant, so that the true and genuine vertical parallax itself, belonging to the given observation and altitude, may result, is not so easy a matter; it surely requires much labour and a fairly ample calculation. Above all, it proved the more laborious for us because it fell to us to pave the way in this field for the first time: for no one, as far as I know, has carried a torch before us in these finer matters. Let us therefore weigh the method of the calculation the more carefully, so that hereafter we may complete the remaining investigations the more readily and quickly.

[Margin: Hoc in exemplo nullâ reductione ad orbitam opus eſt.] *In this example no reduction to the orbit is needed.*

To begin with, then, in the eastern quadrant — namely in the first observation, made at $7^h\ 22^m\ 7^s$ — let the parallax found above, reduced to the orbit, 10′ 19″, be reduced to the vertical; although in this example there is no need at all for any reduction, since this reduction introduces no difference whatever, so that it can safely be omitted this time. But so that you need not take my word for it, we shall examine the matter itself, whether it is so or not; at the same time we shall show, with the following Diagram B and with rules, the way that must always be followed hereafter.

[Margin: Methodus inveniendi parallaxin orbitæ coæquatam, & ad verticalem reductam.] *Method of finding the parallax of the orbit equated and reduced to the vertical.*

Let L A M be the meridian, L M the horizon, P O the equator, Q N the ecliptic, R X the orbit of the comet, C the comet, A C K the circle passing through the comet, B C D the circle of declination, C D the comet's northern declination, K C the altitude of the comet, H the point of intersection of the comet's orbit and the equator, D H C the angle of the orbit and the equator, L K the azimuth, H C D the angle of the orbit and the declination, K C D that of the vertical and the declination, and H C K, or G C I, the angle of the orbit and the vertical, which we now need for carrying out this operation. But this angle cannot be found unless the angle of the orbit and the declination is first investigated from the right-angled triangle H C D, given, namely, the angle of the orbit and the equator for that time, 63° 2′ 0″, and C D, the northern declination of the comet itself: that is, by subtracting the antilogarithm of the side C D, the declination, from the antilogarithm of the angle, so as to have the logarithm of the angle sought, that of the orbit and the declination.

Then let the angle of the vertical and the declination at the comet, B C S, also be explored, from the azimuth K L, or its vertical angle S A B, and the side A B, the comple- ment, namely, of the elevation of the pole. This is done by first finding, in the right-angled triangle A S B, from the angle S A B and from A B, the side S B; and likewise, in the right-angled triangle C S B, from two sides — namely the hypotenuse C B, the complement of the declination, and the side S B just found — the angle sought, S C B, of the declination and the vertical: that is, by taking away the logarithm of the complement of the declination, C B, from the sum of the logarithms of the complement of the altitude and of the azimuth, you will have the logarithm of the angle sought, S C B, or of its vertical angle D C I. Afterwards, let the angle H C D be subtracted from this angle D C I so found, or be added to it, according to the given occasion and the situation of the circles, and the angle I C G sought, of the orbit and the vertical, will come out.

Finally, given the angle I C G and C G, the equated parallax of the orbit, in the right-angled triangle C G I, the hypotenuse C I, the parallax reduced to the vertical, is found from the mesologarithm, by subtracting the antilogarithm

of the angle from the mesologarithm of the side. And so the parallax is made somewhat greater if the angle of the orbit and the vertical is of some notable size; if not, it contributes little, or nothing at all, to the parallax — and we now have such an example at hand.

[Margin: Quid ſit parallaxi[?] orbitæ.] *What the parallax of the orbit is.*

For the parallax of the orbit found above is nothing other, in the attached Figure B, than the space that the same parallax subtends in the comet's orbit R C G H X — from the body of the comet, namely, towards the horizon — that is, C G; and this orbit of the comet, in this example of ours, nearly coincides with the vertical circle R C K drawn through the comet. Therefore the parallax reduced to the vertical, C I, though it is the hypotenuse of the triangle C G I, can become only very slightly greater, because the angle of the orbit and the vertical is too acute. When this angle is given larger, however, the ratio of the reduction of the parallax of the orbit, C G, to the vertical parallax, C I, also becomes more evident. Indeed, to put it in a word, this reduction of ours is nothing but a transfer of the parallax of the orbit, C G, to the vertical circle, C I: namely when, with the help of the angle I C G of the orbit and the vertical, once found, and of the side C G — that is, the assumed parallax of the orbit — the hypotenuse C I of the triangle I C G is explored.

[Margin: Parallaxis verticalis perpetuò major eſt parallaxi orbitæ.] *The vertical parallax is always greater than the parallax of the orbit.*

Since, therefore, C I, being the hypotenuse, is always greater than the side C G, the vertical parallax too is certainly always greater than the parallax of the orbit. In addition, as we pointed out above, every motion completed along an oblique line is always smaller than one carried out along a straight line; and the vertical R C K passing through the comet is the straightest of all with respect to the horizon, since it alone falls at a right angle, and consequently it is also straighter than the orbit itself.

[Margin: Niſi angulus orbitæ & verticalis conſpicuæ ſit magnitudinis,parallaxis orbitæ & verticalis vix quicquam differunt] *Unless the angle of the orbit and the vertical is of conspicuous size, the parallax of the orbit and the vertical parallax hardly differ at all.*

For that reason the parallax reduced to the vertical will also necessarily always be greater than the one completed in the orbit — provided that the angle is of some notable size; otherwise, as we have said, it introduces almost no difference into the parallax of the orbit.

- *Horizon.*: Horizon
- *Æquator.*: Equator

[252] the page sets this calculation as unruled lines, italic labels with roman figures and point-letters, the step numbers 1 and 2 standing at the left, with short rules under the logarithms of the second, fifth and seventh lines. The columns follow the page's alignment, and the blank header row is not printed. Most degree, minute and second figures stand bare on the page; the marks are supplied here in the house form. The word "Sum" stands in the figure column on the page, left of "Log.". The tags *S.* and *Add.* are the page's own; *S.* is not expanded on the page. The calculation continues overleaf with a step numbered 3.

[253] these three lines complete the worked calculation of the previous page, as step 3, in the same unruled layout: italic labels, roman figures and point-letters, the step number at the left. A rule stands under "24 S."; the result 580856 stands below it. Line 2's degree, minute and second figures stand bare on the page; the marks are supplied here in the house form. The tag *S.* is the page's own and is not expanded on the page.

- *Occidens.*: West
- C (below the centre): the diagram's letter
- *Autor ſculpſ.* (lower right of the frame): "The author engraved it."
- No letter S is drawn on this diagram.

You see, therefore, that since the angle of the orbit and the vertical, I C G, came out at only one degree and a few minutes, the parallax of the orbit has not been changed in the slightest by this reduction to the vertical, but has remained the same to the very seconds.

[Margin: Parallaxis verticalis reducta denuò limitanda eſt per proſthaphæreſin inclinationis.] *The parallax reduced to the vertical must be limited again by the prosthaphaeresis of inclination.*

Secondly, this same parallax, found and reduced to the vertical, must likewise be limited and equated in the western quadrant, because in this observation the distance of the comet and the Heel was not exactly parallel to the horizon; instead, the star was somewhat higher than the comet. Hence a certain prosthaphaeresis of inclination arises, and once it is found the whole business will be complete. But this latter inquiry is much more extensive, and it requires an entirely different diagram, one that represents the western configuration of

the comet — that is, of the later observation, at $10^h\ 57^m\ 20^s$ (such as the attached C).

[Margin: Quâ ratione proſthaphæreſis inclinationis eruatur.] *How the prosthaphaeresis of inclination is derived.*

In it, let L A M be the meridian, N Q the ecliptic, T P the equator, G X the orbit of the comet, A B O and A C K vertical circles, S the pole of the world, S B R the circle of declination, B the Heel of Perseus, C the comet, and B C the bare and uncorrected distance of the comet at the later observation. Let D C be a line parallel to the horizon, B D the difference in altitude of the comet and the Heel, C D B the parallactic triangle of the comet's inclination, B C D the angle of inclination, B I the first prosthaphaeresis, and B D the second and corrected prosthaphaeresis of inclination, which we have now set out to investigate for a true and genuine knowledge of the parallax.

[Margin: De proſthaphæreſi inclinationis primâ & ſecundâ.] *On the first and second prosthaphaeresis of inclination.*

For since, in this later observation, the fixed star and the comet did not stand entirely on a line parallel to the horizon, but the fixed star stood higher than the comet, the distance of the two bodies, C B, is not apparent and true at the same time, as it necessarily must be for establishing the true parallax — as was explained at length at the beginning of this Book, p. 170 and following. Next, having subtracted this pseudo-parallel distance B C of the later observation from the vertical distance of the earlier observation, a pseudo-motion also arises in the apparent motion; and so, moreover, when this adulterated apparent motion is compared with the true proper motion taken from the table, the genuine parallax is certainly vitiated in part — and indeed for a greater and a smaller angle of inclination D C B. Therefore it is necessary, as we also laid down at the beginning, that we examine this prosthaphaeresis of inclination, which always adulterates the true parallax, properly and as diligently as possible, so that afterwards, once this prosthaphaeresis is found, we may also correct completely the parallax previously reduced to the vertical, either by adding it or by subtracting from it.

[Margin: Methodus pro ſupputanda proſthaphæreſi inclinationis primâ.] *Method for computing the first prosthaphaeresis of inclination.*

Now let us say by what method the first prosthaphaeresis of inclination should be found. First, let the angle B A C be sought. Two data are indeed given us for finding it: namely the bare observed distance B C, and A C, the complement of the comet's altitude. But since in this oblique-angled triangle A B C two data alone do not suffice, a third must also be computed, namely A B, the complement of the altitude of the Heel at $10^h\ 57^m\ 20^s$ — so that at the same time you will not fail to know how much lower the comet is than the fixed star.

With all the sides of the oblique triangle B A C known, therefore, the angle B A C is sought in the usual way: let the difference of the two sides enclosing the sought angle be added to and subtracted from the third side; from the aggregate

of the logarithms belonging to the two sides just mentioned (those enclosing the sought angle), the half-remainder is the logarithm of the half-angle sought.

But if you also have the azimuth of the comet and of the fixed star known right from the start, this angle is derived by a much shorter way. For if the azimuths are given in one and the same quadrant, you will at once obtain the sought angle B A C itself from their simple difference; but if the azimuth of each is found in a different quadrant, the sum of the complements of each azimuth to 90° is the angle sought — or, what is the same, let the aggregate of the azimuths be subtracted from the semicircle, and the remainder is the angle sought, B A C.

2. In the same obtuse-angled triangle A B C, given the angle B A C just found, B A, the complement of the altitude of the fixed star, and also B C, the bare observed distance of the comet, let the angle B C A be investigated. By taking away the logarithm of the distance B C from the aggregate of the logarithms of the angle B A C and of the complement of the altitude of the Heel, A B (if, that is, the fixed star is higher than the comet; otherwise take the complement of the altitude of the comet), you will find the angle sought, B C A.
3. Let the angle D C A likewise be sought, in the triangle A D C, which is entirely acute-angled. We shall find it conveniently by dropping the perpendicular C H from the comet C onto the vertical of the fixed star, or, what is the same, the perpendicular D E from D onto the vertical of the comet. These two perpendiculars, C H and D E, are always entirely equal. For since D and the comet C are removed from the horizon by an equal space — or, what comes to the same, are equidistant from the vertical point A — the angles A D C and A C D must both be of exactly the same size. Since, therefore, A D and A C are similar sides, and each perpendicular is derived (as you will soon perceive) from the common angle D A C and an equal side, either A D or A C, certainly the perpendiculars must also be entirely equal — something it is not out of place to know properly here, since otherwise it is easy to stumble in the course of the calculation. Since, therefore, the said perpendiculars are of the same size as each other, seek just one of them, whichever you like, from the angle B A C and the complement of the comet's altitude (because the comet is lower than the fixed star; otherwise let the complement of the fixed star's altitude be used), by adding the logarithms. Likewise seek the side A E, in the right-angled triangle A E D, by subtracting the antilogarithm of the perpendicular D E just found from the antilogarithm of the complement of the comet's altitude, A C, or rather of A D, which is equal to it. Then, when the side A E is taken away from A C, E C will remain. Finally, in the right-angled triangle D E C, from E C and the perpendicular D E — namely the two sides that form the right angle — let the sought angle D C A be found, or C D A, which is wholly equal to the other. Then take away the angle B C A, found in step 2, from this

D C A, and you will have the angle of inclination D C B itself, which was to be sought this time.

[Margin: Mediante angulo inclinationis invenitur ultim⟦a/â⟧ æquatio parallaxeos.] *By means of the angle of inclination the final equation of the parallax is found.*

4. Once this angle is at last found, the way lies open to us to that final limitation, or equation, of the parallax, in this manner. Let the perpendicular B I be dropped, in that parallactic triangle B D C, from the fixed star B (because here it is the higher) onto the line D C parallel to the horizon; this serves us as the prosthaphaeresis of inclination — namely, by how much the vertical parallax found above should have been greater on account of this inclined distance B C. For the comet, while it was by no means equidistant from the horizon with the star, but much below the fixed star, certainly makes this distance somewhat greater, with respect to the parallax that depresses the comet, than it really was in this later observation. And since, with the comet engaged in approaching the fixed star, as you have perceived, the later distance is always smaller than the earlier, and since, when the one is subtracted from the other, it is certain that the mean parallax results: therefore, if the later distance is greater than it ought to be, the parallax will come out smaller than if the later distance were smaller. This is what also happened in this case, if you perceive the matter rightly; and so, consequently, the prosthaphaeresis B I that is to be sought will have to be added to the previous parallax reduced to the vertical.

[Margin: Proſthaphæreſis hâc vice adjectiva eſt.] *This time the prosthaphaeresis is additive.*

This prosthaphaeresis of inclination B I is easily found from the logarithm in the following way: take the parallax reduced to the vertical above in place of B C, in that parallactic triangle B D C, and then use the angle of inclination D C B derived in step 3, adding the logarithm of each. Finally, once the prosthaphaeresis B I is found, let it be added this time to the parallax reduced to the vertical, and the genuine parallax, first equated, will come out. First equated, I say: for if we consider the matter still more deeply, this prosthaphaeresis B I is not in every respect the true and genuine one belonging to this observation; B D is. For the comet has been depressed by parallax in the vertical circle, and the distance B C has been corrupted not along the perpendicular line B I but along the vertical B D. For this reason B D too must be sought and added to the same parallax reduced to the vertical, so that the genuine vertical parallax itself, equated a second time, may be derived. But by what way this later, second prosthaphaeresis B D ought to be investigated will be told afterwards, once we have first said something about the axioms of prosthaphaereses that are supremely necessary for this business.

[Margin: Parallaxis primò coæquata.] *The parallax first equated.*

[Margin: An proſthaphæreſis addenda, an verò ſubtrahenda ſit ? haud cuivis tam promptè percipi datur.] *Whether the prosthaphaeresis is to be added or rather subtracted is not something just anyone can perceive so readily.*

You will have understood, however, I think, from what has been said here and there, that the parallax reduced to the vertical, on account of the comet's so varied situation with respect to the fixed star in this later observation, when the distance is not given entirely parallel to the horizon, is vitiated in different ways, being made now greater, now smaller; and hence the prosthaphaeresis of inclination, by which that parallax is remedied, is now to be added, now to be subtracted. But as to when it is of this or that character — truly, I frankly confess, the matter calls for a deeper inquiry and is very difficult to perceive, so that it is not granted to just anyone here to go to Corinth, but only to one most skilled in the celestial mysteries, who examines and weighs the whole matter with the utmost powers of his mind; for the rest, it is nearly impossible to attain these things without a Delian diver (as the proverb usually says). So, for their sake, let us present certain axioms, directed for the most part to our comet and put together by me with no small labour, from which it will at once be clear, without any error or tedium, whether the prosthaphaeresis — the first as well as the second (for they are always of the same quality) — is additive or rather subtractive, in any given position whatever of the comet and the fixed star. From this, certainly, no little help will flow to all who are occupied in this business of parallaxes; but if these axioms are not known, the matter turns out quite obscure and is scarcely perceived, and by rather few.

[Margin: Autor certa axiomata conſtruxit,quorum beneficio cuilibet illicò cognoſcere datur, cujus affectionis ſit proſthaphæreſis tam prima quàm ſecunda in[?]linationis.] *The author has constructed certain axioms, by means of which anyone may at once know of what character the prosthaphaeresis of inclination [?] is, the first as well as the second.*

[Margin: Axiomata ſequentia,quibus caſibus conveniant.] *The following axioms: to which cases they apply.*

[Margin: Quando proſthaphæreſes contrariæ fiant denominationis.] *When the prosthaphaereses become of contrary denomination.*

[Margin: Quando fixæ ad Cometam ſub angulo recto exiſtunt, aliis diverſis planè axiomatibus opus eſt.] *When the fixed stars stand at a right angle to the comet, other, entirely different axioms are needed.*

The following axioms, however, are constructed for those cases in which the fixed stars lie either beneath the comet's orbit itself or very near it; and in addition — mark this well — when the distance at the earlier observation is found under practically one and the same vertical, while the distance at the later observation is found roughly parallel to the horizon. But if the contrary has occurred — namely, when the distance of the earlier observation is found parallel and that of the later one vertical — each prosthaphaeresis of inclination will have to be applied, according to the axioms set out below, in the contrary way: that is, the additive becomes subtractive, and vice versa — that is, where

the fixed stars lie beneath the comet's orbit itself, or near it. Where, however, the fixed stars are found at roughly a right angle to the comet and its orbit, the case with this prosthaphaeresis of inclination is truly very different, and special axioms are needed. But we shall speak about these at length in connection with Investigation IX, when an example of that kind will be put forward, in which the fixed star viewed the comet at a right angle.

Axioms of Parallaxes with Respect to Addition and Subtraction: namely, when the fixed stars lie beneath the orbit itself or near it, that is, at a very acute angle to the comet; and moreover, with the distance roughly vertical in the earlier observation, and the distance roughly parallel to the horizon in the later observation [Axiomata Parallaxium ratione additionis, & ſubtractionis : quando nimirùm Stellæ Fixæ ſub ipsâ orbitâ, vel propè eam reſident, ſub angulo ſcilicet admodùm acuto ad Cometam : adhæc in priori obſervatione, datâ diſtantiâ circiter verticali, & in poſteriori obſervatione diſtantiâ circiter horizonti parallelâ.]

[Margin: Axioma primum.] *The first axiom.*

1 When the comet in the east, or in the first, vertical observation, is lower than the fixed star and approaching it; and likewise, in the west, or in the later, parallel observation, the comet is lower in altitude both than the fixed star and than the perpendicular line falling from the fixed star onto the comet's vertical, the prosthaphaeresis of inclination is additive. Conversely, when in the west, or in the second, parallel observation, the comet is higher than the fixed star, and the line per- pendicular, the prosthaphaeresis is subtractive; but if the comet is lower than that perpendicular line, although it appears higher than the fixed star, the prosthaphaeresis is additive.

[Margin: Axioma ſecundum.] *The second axiom.*

2. When the comet in the east, or in the earlier, vertical observation, is higher than the fixed star and the perpendicular line, and is approaching it; and conversely, in the western region, or in the later, parallel observation, the comet is lower than the fixed star in altitude, then the prosthaphaeresis of inclination is to be subtracted. But it is to be added when the comet in this western region, namely in the parallel observation, is higher than the fixed star and the perpendicular line. But if the comet is lower than the perpendicular line, although it appears higher, the prosthaphaeresis is subtractive. And if in the east, in the roughly vertical observation, it is below the perpendicular, although higher than the star, and in the west lower, the prosthaphaeresis is additive.

[Margin: Axioma tertium.] *The third axiom.*

3. When the comet in the east, namely in the earlier, vertical observation, is lower than the fixed star and receding from it; and then in the west, namely in the second observation, the comet is lower than the fixed star in altitude, the prosthaphaeresis of inclination is additive. It is subtractive, however, if in the west, namely in the second observation, the comet is higher than the fixed star and the perpendicular line; but if in the

west, namely in the second observation, the comet is lower than the perpendicular line, although higher than the star, the prosthaphaeresis is additive.

[Margin: Axioma quartum.] *The fourth axiom.*

4. When the comet in the east, in the earlier, vertical observation, under one and the same vertical circle, is higher than the fixed star and the perpendicular line falling from the fixed star onto the comet's vertical, and is approaching it; and conversely, in the west, in the later, parallel observation, the comet is lower than the fixed star in altitude, the prosthaphaeresis of inclination is subtractive. But in the west, in the later observation, when it is higher than the fixed star and the perpendicular line, the prosthaphaeresis is additive. But if in the east, namely in the earlier, vertical observation, it is lower than the perpendicular line, although the star stands higher, while in the west, in the later, parallel observation, it is above the fixed star and the perpendicular, the prosthaphaeresis is subtractive.

[Margin: Axioma quintum.] *The fifth axiom.*

5. When the comet in the east, in the earlier, vertical observation, is higher than the fixed star and the perpendicular and is receding, but with each phenomenon standing under different verticals; and conversely, in the west, in the later, parallel observation, it is above the fixed star and the perpendicular, the prosthaphaeresis is subtractive. But in the later observation, with the comet below the fixed star, the prosthaphaeresis is additive; but if it is above the perpendicular, although the comet appears below the fixed star, the prosthaphaeresis is subtractive.

When, however, the contrary occurs, it must then be noted that, where the first observation, or distance, was vertical in the west, and the later one, in the eastern region, was taken as parallel, the prosthaphaeresis of inclination, as we have already mentioned above, takes on the contrary effect with respect to addition and subtraction.

More cases, and other ones, could indeed still be given for some other comets; but since this business would be too lengthy, and I would overwhelm the reader too much, I deliberately do not wish to extend these axioms further. Nor, truly, is it much to the purpose: for from those just put forward I hope that the characters of the prosthaphaereses for each and every case will easily be understood by philo-mathematicians who weigh the matter duly and accurately. But so that at a single glance

[Margin: Hæc axiomata quanquam non ſunt omninò univerſalia,poſſunt tamen ad quoscunq; caſus ab attento harum rerum ſtudioſo facilè extendi.] *Although these axioms are not entirely universal, they can nevertheless easily be extended to any cases whatever by an attentive student of these matters.*

everything contained in the preceding axioms may be evident, I have constructed a small table, by means of which, in all these cases — once it is known, that is, in which region of the sky each distance was observed; then the comet's

place with respect to recession and approach; likewise with respect to the perpendicular and the fixed star, namely whether the phenomenon stands above or below it — you will recognize without labour of what character the prosthaphaeresis is, to be added or to be subtracted.

	Below the fixed star, approaching.	Above the fixed star and the perpendicular, approaching.	Above the fixed star but below the perpendicular, approaching.	Below the fixed star, receding.	Above the fixed star and the perpendicular, receding.	Above the fixed star but below the perpendicular, receding.	Above the fixed star and the perpendicular, receding.
Below the fixed star and the perpendicular.	The prosthaph. is additive.	Subtractive	Additive.	Additive.	Subtractive	Subtractive	Additive.
Above the fixed star and the perpendicular.	Subtractive	Additive.		Subtractive	Additive	Subtractive	Subtractive
Below the fixed star and above the perpendicular.							Subtractive.
Above the fixed star but below the perpendicular.	Additive	Subtractive	Additive.	Additive	Subtractive		

254

With these axioms thus handed down, let us proceed with our calculation, namely by inquiring into the prosthaphaeresis of inclination B I itself. Therefore let the altitude of the Heel at the later observation first be computed.

1. To find the altitude of the Heel. For the 23rd day, at $10^{h}\ 57^{m}\ 20^{s}$.

254 the table is ruled. A head in roman, "Cometâ in priori obſervatione verticali exiſtente." (With the comet in the earlier, vertical observation), spans the first six value columns; a boxed head, "Cometâ v. & Fixâ in priori obſerv. ſub diverſis verticalibus exiſtentibus." (With the comet *v.* and the fixed star standing under different verticals in the earlier observation), stands over the seventh column alone. A label set vertically beside the row heads, "Cometâ in poſteriori parallelâ obſervatione exiſtente." (With the comet in the later, parallel observation), spans the four rows. The column heads describe the comet in the earlier observation, the row heads the comet in the later observation. Empty cells are empty on the page.

Right ascension of the Sun			273° 8′ 57″			
Elongation from the meridian			164° 20′ 0″			
			437° 28′ 57″			
Right ascension of the Heel			50° 39′ 37″			
			386° 49′ 20″			
Excess over 360, distance from the meridian			26° 49′ 20″	Logarithm	79578	
Declination of the Heel			31° 7′ 38″	Antilogarithm	15546 *A.*	
	BF			Logarithm	95124	22° 43′ 19″
Logarithm of the declination	BR	65983

Antilogarithm	SF	57904	55° 54′ 51″			
Complement of the elevation of the pole	S A		35° 37′ 0″ *S.*			
	AF		20° 17′ 51″	Antilogarithm	6411	
	BF			Antilogarithm	8079 *A.*	
Antilogarithm of A B, or logarithm of	B O				14490	59° 53′ 40″ Altitude of the Heel.
				Altitude of the comet		50° 43′ 15″
				Difference, or angle DBC		9° 10′ 25″

[255]

Since, then, the altitude of the Heel is given as 9 degrees greater than the comet's, the distance B C is in no way parallel to the horizon; rather, it forms the angle of inclination D C B, which let us now explore by calculation.

2. To compute the angle B A C.

B C, distance of the comet and the Heel, uncorrected	14° 7′ 23″	Given from the calculation above, p. 183				
Altitude of the comet at $10^h\ 57^m\ 20^s$	50° 43′ 15″	Its complement	C A	39° 16′ 45″	Log.	45712
Altitude of the Heel, B O	59° 53′ 40″	Its complement	B A	30° 6′ 20″	Log.	68997 *A*

[255] the calculation is set unruled, in the page's own columns: italic labels, roman figures and point-letters; short rules stand under the figures that are added or subtracted. The degree, minute and second marks are printed over the first figure row and over the rows giving 22° 43′ 19″, 55° 54′ 51″ and 59° 53′ 40″; the other rows stand bare on the page, and the marks are supplied here in the house form. The tags *A.* and *S.* are the page's own and are not expanded on the page. The figures 360 in the label of the sixth row are printed bare.

4. For the first prosthaphaeresis of inclination.

Parallax reduced to the vertical	0° 10′ 19″	Log-a-rithm	580856		
Angle of inclination D C B	40° 15′ 0″	Log-a-rithm	43676 *A.*		
Prosthaphaeresis of inclination B I, first, or equal			624532	6′ 40″	
The parallax reduced to the vertical was				10′ 19″	Add.
Therefore the vertical parallax, first equated, becomes				16′ 59″	for the altitude of the comet, 44° 28′, namely at 7^{h} 22^{m} 7^{s} in the evening, on December 23.

Since, however, this prosthaphaeresis B I that has been found is not yet the true and genuine one, but B D is, as you have perceived, this one too must therefore now be sought.

[Margin: Methodus calculi pro parallaxi verâ ſecundò coæquatâ verticali.]
Method of calculation for the true vertical parallax, equated a second time.

But usually so very small a difference is observed between B I and B D that it hardly repays the labour of the calculation, especially when B I is only of one minute or another. Lest we should be the more negligent in this part of the calculation on that account, however, let us append both the method of the calculation itself and the calculation itself. 1. In diagram C above, then, let the angle D B C be sought in the right-angled triangle C H B, by means of the perpendicular C H found above, which is entirely equal to D E, and of B C, the

[257]set unruled, as the step above. The signs + and — after three of the logarithms are the page's own. The figure 3 in the label "Side 3 B C" is printed so and is not explained on the page.

distance of the comet and the fixed star: that is, by subtracting the logarithm of this one from the logarithm of the other, the logarithm of the angle H B C, or D B C, will come out. 2. Let the true B I be investigated from the distance B C and the angle of inclination D C B, by adding their logarithms. 3. The angle C B I, in the right-angled triangle C I B: subtracting the mesologarithm of C B (cossically, if need be) from the mesologarithm of the perpendicular B I, the remainder is the antilogarithm of the angle C B I; and this, always subtracted from the angle D B C found in step 1, produces the angle I B C. 4. In that smaller, acute-angled triangle B I C, let B D, the second prosthaphaeresis, finally be sought in this way: from B I, namely the first prosthaphaeresis, and the angle I B C just found, by subtracting the antilogarithm of the angle from the mesologarithm of the side B I, the first prosthaphaeresis, there will remain the mesologarithm sought, that of B D, the second prosthaphaeresis of inclination. Afterwards, according to the situation of the comet with respect to the fixed star, let this prosthaphaeresis be added to, or subtracted from, the parallax reduced to the vertical, derived on p. 191, following the axioms above; and you will obtain the true vertical parallax, equated a second time, for a certain given altitude of the comet.

[Margin: In inquiſitione proſthaphæreſeos poſterioris tutò ſcrupula ſecunda omitti posſunt.] *In the inquiry into the later prosthaphaeresis the seconds can safely be omitted.*

Here it should be noted that in this inquiry into the later prosthaphaeresis there is no need to use seconds, but only minutes, since the matter comes to the same thing; nor does it add anything in the seconds to the second prosthaphaeresis, or take anything away, as will be clearly evident to anyone who examines the following calculation, even though the prosthaphaeresis there amounts to nearly 7 minutes. This time, however, let us extend the calculation to seconds, but in future let us spare ourselves that labour.

1.	Logarithm of the hypotenuse C B, distance of the comet and the Heel	14° 7′ 23″	Logar.	141057 *S.*	
	Perpendicular C H, which equals D E	11° 56′ 26″	Logar.	157554	
	Angle H B C, or D B C		Logar.	16497	57° 59′ 10″ D B C
2.	Hypotenuse C B, distance of the comet and the Heel	14° 7′ 23″	Logar.	141057	
	Angle of inclination D B C	40° 15′ 0″	Logar.	43676 *A.*	
	Perpendicular B I		Logar.	184733	9° 4′ 16″ B I

4.	Prosthaphaeresis of inclination, equal	6′ 40″	Mesol.	624532	
	Angle I B D just found	7° 22′ 17″	Antil.	830 *S.*	
	Prosthaphaeresis of inclination, equated a second time		Mesol.	623702	6′ 43″ *A.* According to axiom 1.
	The parallax reduced to the vertical, however, was				10′ 19″
	Therefore the true vertical parallax, equated a second time, is				17′ 2″ For the altitude of the comet, 44° 28′, observed at 7^{h} 22^{m} 7^{s} on December 23.

258

[Margin: Novâ ratione differentiam parallaxium eruere.] *To derive the difference of the parallaxes by a new method.*

Finally, with this genuine vertical parallax, equated a second time, found in this way, we shall now also show, likewise by a new method, how the difference between the parallaxes of two given altitudes of the comet can be derived: provided that the angle D C B (when the comet is above the fixed star), or the angle A C B (when the comet is below the fixed star, as in this example of ours), which the line of distance and the vertical of the comet form, does not exceed 30, or at most 40 degrees. If it is much greater, you will by no means be able to determine the parallax so precisely at each altitude, especially if there is some notable parallax.

First, then, just as in the earlier, eastern observation we reduced the parallax of the orbit to the vertical, so in this later, western observation too let that same parallax of the orbit, 10′ 19″, be reduced to the vertical by the same method: subtract the antilogarithm of the angle A C B, found in step 3 of the first prosthaphaeresis, from the mesologarithm of the parallax of the orbit, and you will have the mesologarithm + of the parallax reduced to the vertical, for the

[258] the calculation is set unruled, in the page's own columns: italic labels, roman figures and point-letters; short rules stand under the figures that are added or subtracted. The degree, minute and second marks are printed only over the first figure rows; the other rows stand bare on the page, and the marks are supplied here in the house form. The signs + and the tags *A.* and *S.* are the page's own. The label of the fifth row prints the angle of inclination as "D B C", where the prose above names it "D C B"; kept as printed. "According to axiom 1." is set on two lines joined by a printed bracket.

altitude of the comet in the later observation. Take this away from the parallax reduced to the vertical for the earlier altitude, found on p. 186, and there will remain the difference of the parallaxes itself, applicable to both altitudes. This difference, in turn, subtract from the genuine parallax equated a second time that has been found, when the comet is higher at the later altitude than in the earlier observation; but if the comet's altitude in the later observation is lower, add it to the parallax just mentioned. In this way you will establish the true and genuine vertical parallax, equated a second time, for the later altitude of the comet.

[Margin: Præſtat ad certam altitudinem parallaxin, quàm ejus differentiam elicere.] *It is better to derive the parallax for a certain altitude than its difference.*

Meanwhile, however, I advise that, whenever it can be done, you examine the parallax for one certain altitude with the aid of the prosthaphaereses (a method I prefer to this one); but where the observations do not permit this at all, you may use this difference of parallax, and you will proceed safely, unless the said angle A C B, as I have already warned, grows too large. In our example set out here, although that angle turned out to be still a little greater than 40 degrees, it nonetheless gives the genuine vertical parallax for the earlier altitude of the comet almost the same as from the prosthaphaereses, and scarcely two seconds smaller. Let this serve you as a test; and it is proof that the difference of parallax has been derived by our method correctly and properly.

Parallax of the orbit	0° 10′ 19″	Mesolog.	80880		
			+		
A C B, of the angle	42° 12′ 18″	Antilog.	30009		
			+ *S.*		
Parallax reduced to the vertical		Mesolog.	50871	13′ 56″	of the later observation
			+		
The parallax reduced to the vertical, of the earlier observation, was				10′ 19″	
Therefore the difference of the parallaxes between the altitudes 44° 28′ and 50° 53′				3′ 37″	Subtract, because the comet is higher in the later observation.
True vertical parallax, equated a second time, for the altitude 44° 28′				17′ 2″	
Therefore the parallax for the later observation, at the comet's altitude 50° 43′ 15″				13′ 25″	

259

[259] the calculation is set unruled, in the page's own columns: italic labels, roman figures and point-letters; short rules stand under the figures that are subtracted. The degree, minute and second marks are printed only over some rows; the other rows stand bare on the page, and the marks are supplied here in the house form. The signs + and the tag *S.* are the page's own. "In the later observation" is printed on the following line, as a turn-over of "Subtract, because the comet is higher".

[Margin: In majorem rei fidem ex diverſis inſuper aliis obſervationibus ſimili methodo parallaxis pro die 23. Dec. ſupputetur.] *To make the matter more credible, let the parallax for December 23 be computed by a similar method from further, different observations as well.*

But so that we may be all the more secure, we do not wish to rest content with this single calculation, set out for this 23rd of December; rather, let us add four more calculations, from entirely different observations made at different times, examining in this second, following inquiry the parallax now from entirely other distances, namely those of the comet and the bright star of Medusa; retaining, however, the earlier observation, at $7^h\ 22^m\ 7^s$, since in the eastern quadrant, at about that time, no other observation was made in which the comet stood together with Algol under one and the same vertical. In place of the later observation of the earlier calculation, however, let us take the one made at $11^h\ 28^m\ 0^s$, in which the said distance was found still more convenient, as being more nearly parallel to the horizon, than the later distance of the comet and the Heel of Perseus in the preceding calculation. From this inquiry, therefore, we hope for a parallax that is almost more accurate still, especially because the fixed star, namely the bright star of Medusa, stood almost beneath the orbit itself, removed from it by scarcely a few minutes.

Diagram. Diagram D, engraved and set in the text at the left. From an apex A at the top two arcs and a straight line descend to a horizontal line, the ecliptic, on which B, C, H and G stand from left to right. A straight line, the orbit, crosses from the upper right. D, F and E stand on one level, joined by dotted lines, E marked with a small star; a line, the comet's, runs from E down to the left. Below the ecliptic two points marked with small circles are lettered L and I. A large capital D, the figure's own letter, stands to the right of L, and the engraver's signature stands at the lower right.

- A (apex, top): A
- Orbita (along the straight line from the upper right): "Orbit"
- D (left, on the level of F and E): D
- F (middle, on the same level): F
- E (right, with a small star): E
- Cometa (along the line from E): "Comet"
- Ecliptica (right end of the horizontal line): "Ecliptic"
- B, C, H, G (under the horizontal line, left to right): B, C, H, G
- L (below the ecliptic, with a small circle): L
- D (large capital, right of L): the figure's letter D
- I (lowest point, with a small circle): I
- Aut ſculps. (lower right, script): the engraver's signature, as printed

For the rest, since the distances of the comet and Algol, on which we must now rely, are not yet known to us from observation, they must first be derived by calculation, as we did in the earlier inquiry, namely from the altitudes and azimuths, following this diagram D. It agrees with diagram A above in almost everything, except that in this position of the comet the bright star of the Head

of Medusa stood toward the west with respect to the orbit. There is therefore no need to repeat the lines and letters one by one again, either of this figure or of all the remaining figures that follow; so let us set to work at once.

Therefore the fictitious or mean parallax		13′ 49″			

262

[Margin: Parallaxis media.] *The mean parallax.*

It would hardly be worth the effort to reduce these distances to the orbit, correcting and limiting them for the apparent motion, since the fixed star is so very close to the orbit that it is removed from it by scarcely a few minutes; and we also learned from the earlier calculation that there was scarcely 15″ of difference between the limited apparent motion and the fictitious one, although at that time the Heel stood a whole degree and more from the orbit. Nevertheless, so that you are not left in doubt whether this limitation can contribute even the least thing to the fictitious parallax, I shall not mind entering upon the calculations themselves on this matter, and indeed by the third method given above, the easiest of all, and the most suitable for distances in which the fixed

[261] set as the calculation above. "south" renders the page's *Auſt.*

[262] the calculation of p. 250 continues here, set unruled in the page's own columns: italic labels, roman figures and point-letters; short rules stand under the figures that are added or subtracted. 263

[Margin: Parallaxis Orbitæ cum mediâ planè eadem eſt hocce in exemplo.] *In this example the parallax of the orbit is entirely the same as the mean parallax.*

[263] set as the calculation above. ♉ is the page's sign of Taurus. The decimal points in the logarithms of the last rows are the page's own. The page prints "Rectat angulus" in the label rendered "There remains the angle"; the sense is that of "Restat".

From this it is perfectly clear, as we said at the beginning, that this parallax of the orbit is entirely the same as the fictitious, or mean, parallax, exceeding it by scarcely a single second; so that there would have been no need to carry out this limitation here. Indeed, even if you undertake the matter by the other methods, you will still extract no difference.

[Margin: Reducatur parallaxis Orbitæ ad verticalem.] *Let the parallax of the orbit be reduced to the vertical.*

Let us now go on with the calculation, however, and reduce this parallax of the orbit that has been found to the vertical, since we do not know whether the comet stood together with Algol precisely under one and the same vertical. But it is a great help to us that we already know, from the calculation above, from Figure B, the angle H C A, or I C G, of the orbit and the vertical, for 7^{h} 22^{m} 7^{s} in the evening: 1° 15′ 20″. It is therefore easy to reduce the parallax to the orbit.

Mesolog. of the side C G, or the parallax of the orbit	13′ 50″	551549 +	Subtract cossically.	
Antilog. of the angle I C G	1° 15′ 20″	24 +

264

[Margin: Pro Proſthaphæreſi inclinationis inveniendâ.] *For finding the prosthaphaeresis of inclination.*

Next, for this parallax reduced to the vertical, let the corresponding prosthaphaeresis of inclination also be sought, so that the genuine equated vertical parallax may come out. For since the later distance, in the west, was not altogether parallel to the horizon, as indeed it necessarily should have been, both the first and the second prosthaphaeresis of inclination must be inquired into, as we did above; and both of them, likewise, are to be added according to axiom 1. Before we get there, however, let the altitude of Algol at 11^{h} 28^{m} 0^{s} in the evening be investigated first, and the rest in consequence.

At the comet's altitude of 44° 28′, observed at $7^h\ 22^m\ 7^s$ on December 23.[269]

[Margin: Majoris certitudinis gratiâ denuò parallaxis ad eandem altitudinem inveſtigetur.] *For greater certainty, let the parallax be investigated again at the same altitude.*

And although this parallax agrees closely enough with the one found before, let us nevertheless go on to seek the parallax at exactly the same altitude from

[268] set as the calculation above. The tags *A.* and *Add.* are the page's own and are not expanded on the page.

[269] set as the calculation above; the part figures 1–4 stand at the left margin. The page subtracts 70° 13′ 0″ (C B I) from 85° 11′ 40″ and prints the remainder, the angle I B D, as 4° 58′ 40″; the difference of the two printed figures is 14° 58′ 40″. All three figures are printed as given here, and the next row repeats 4° 58′ 40″.

other observations in turn: keeping, indeed, the earlier vertical observation at $7^h\ 22^m\ 7^s$, but taking, in place of that later one obtained at $11^h\ 28^m$, an entirely different one, made at the hour namely $1^h\ 27^m\ 30^s$ of the 24th day; at which time the altitude and azimuth are likewise given; although in this observation, which is roughly parallel, a far smaller altitude, and on the other hand a far greater azimuth, was observed than in the preceding calculation. From these observations, I say, we shall hunt the matter down for the sake of greater certainty, investigating, therefore, the distances of the comet and the Heel again, so that from so great a variety the truth may become known the more correctly. But there is no need now to explore the earlier distance of the comet and the Heel again, because it was already computed in the first investigation, for the same time; only the later one, at $1^h\ 27^m\ 30^s$ in the morning, on the 24th.

Investigation of Parallax III, for December 23 [Inveſtigatio Parallaxeos I I I. Ad diem 23 Decembris.]

1.

On the 23rd, observation 1, at $7^h\ 22^m\ 7^s$ in the evening	Altitude of the comet	44° 28′	Azimuth	48° 19′ east	Vertical
On the 24th, observation 2, at $1^h\ 27^m\ 30^s$ in the morning	Altitude of the comet	33° 36′	Azimuth	75° 9′ west	parallax.

Longitude of the comet at $1^h\ 27^m\ 30^s$		28° 46′ 25″ ♑	Latitude of the comet		0° 57′ 21″ south
Longitude of the Heel		26° 17′ 12″ ♑	Quadrant of the circle		90° 0′ 0″
Difference, or angle E A K		2° 29′ 13″	Side A L		90° 57′ 21″
Logarithm of the complement of the latitude of the Heel, A E	2259	A E		Antil.	155975
Logarithm of the angle E A K	312748				
Logarithm of the perpendicular E K	315007	2° 27′ 21″		Antil.	92 *S.*
				Antil.	155883 A K 77° 51′ 23″
Antilogarithm K L	2636.640				A L 90° 57′ 21″
Antilog. of the perpendicular E K	91.897 *A.*				K L 13° 5′ 58″
Antilog. of the distance E L	2728.537	3° 19′ 25″	of the comet and the Heel.		
Earlier distance		15° 22′ 0″			
Apparent proper motion		2° 2′ 35″			
Proper motion from the table, for $6^h\ 5^m\ 23^s$ in the evening		1° 47′ 10″	and since this is less than the apparent motion, there is therefore given		

a parallax, by Theorem 1.	0° 15′ 25″

270

2. For the reduction to the orbit: since both the distance of the Heel from the comet's orbit and also the earlier, limited distance of the comet are already known, the calculation is therefore completed without any trouble.

Antilog. of the distance E L	13° 19′ 25″	2728.537	
Antilog. of the distance of the Heel from the orbit, E F		22.528	
		S.	
Antil. of the later distance, reduced to the orbit		2706.00913° 16′ 9″	
The earlier distance, corrected and reduced, was			15° 19′ 10″
The apparent motion, reduced and corrected			2° 3′ 1″
True motion from the table, corresponding to the time between the two observations			1° 47′ 10″
Therefore the true parallax, reduced to the orbit			15′ 51″

271

3. The reduction of the parallax to the vertical is also carried out with no great labour, since the angle of the orbit and the vertical, I C G, in diagram B above, has already become known on p. 191.

Mesolog. of the side C G, or the parallax of the orbit	15′ 51″	537940 +	*S.* cossically.	
Antilog. of the angle I C G, found above	1° 15′ 20″24 +			
Mesolog. of the parallax C I, reduced to the vertical		537916 +	15′ 51″	differs not at all from the parallax of the orbit above.

272

[Margin: Pro Proſthaphæreſi inclinationis.] *For the prosthaphaeresis of inclination.*

[270] set unruled, in the page's own columns: italic labels, roman figures and point-letters; short rules stand under the figures that are added or subtracted. The degree, minute and second marks are printed only over some rows; the others stand bare on the page, and the marks are supplied here in the house form. ♉ is the page's sign of Taurus. The tags *A.* and *S.* are the page's own and are not expanded on the page. "Vertical" and "parallax." stand one under the other at the right of the two observation lines. The "6 5′ 23″" of the proper-motion row is the interval between the two observations; the page sets "in the evening" after it.

[271] set as the calculation above.

[272] set as the calculation above; the signs + are the page's own. The words "differt planè" stand at the end of the last row and run on into the line beneath, "nihil à ſuperiori parall. orbit."

But for finding the prosthaphaeresis of inclination we cannot use any short cut here: for since these things fall to us to be worked out from an entirely new observation, namely at $1^h\ 27^m\ 30^s$, everything must be computed in order, according to our procedure; and indeed first the altitude of the Heel, so that we may not be ignorant whether the comet or the Heel stood higher.

1. To find the altitude of the Heel, at $1^h\ 27^m\ 30^s$, on December 24.

Right ascension of the Sun		273° 15′ 54″				
Elongation from the meridian		201° 52′ 30″				
Right ascension of the midheaven		475° 8′ 24″				
Right ascension of the Heel		50° 39′ 37″				
		424° 28′ 47″				
Excess over 360°, distance from the meridian		64° 28′ 47″	Logar.	10268		
Declination of the Heel		31° 7′ 38″	Antilog.	15546 *A.*		
			Logar.	25814	B F	50° 34′ 40″

Complement of the elevation of the pole, S A		35° 37′ 0″				
A F		6′ 30″	Antilog.	0		
		B F	Antilog.	45409		
		B O, logarithm, or A B	Antilog.	45409	39° 25′ 18″	Altitude of the Heel.
					33° 36′ 0″	Altitude of the comet.
			Difference of the altitudes		5° 49′ 18″	

273

2. To compute the angle B A C.

[273] set unruled, in the page's own columns: italic labels, roman figures and point-letters; short rules stand under the figures that are added or subtracted. The degree, minute and second marks are printed only over some rows; the others stand bare on the page, and the marks are supplied here in the house form. The A F row prints "6 30" with no degree figure, under the minutes and seconds of the rows above; it is given here as 6′ 30″, with no degree figure supplied. The tags *A.* and *S.* are the page's own and are not expanded on the page.

Complement of the altitude of the comet, C A	56° 24′ 0″	Log.	18282	
Complement of the altitude of the Heel, B A	50° 34′ 42″	Log.	25814 *A.*	
Difference of the altitudes	5° 49′ 18″	Log.	44096	Earlier aggregate.
Bare distance of the Heel and the comet	13° 19′ 10″			
Sum	19° 8′ 24″			
Half	9° 34′ 14″	Logar.	179418	
Remainder	7° 29′ 52″			
Half	3° 44′ 56″	Logar.	272749 *A.*	
	Later aggregate		452167	
	Earlier aggregate		44096 *S.*	
	Difference		408071	Logarithm of the half-angle.
	Half		204035	7° 28′ 7″
			Angle B A C	14° 56′ 14″

274

3. Investigation of the angle B A C, D C A, and of the angle of inclination.

Of the angle B A C	14° 56′ 14″	Log.	135573		
Complement of the altitude of the Heel	50° 34′ 42″	Log.	25814 *A.*		
		Log	161387		
Side B C, distance	13° 19′ 10″	Log.	146802 *S.*		
Of the angle B C A		Log.	14585	59° 58′ 4″	B C A
Angle B A C	14° 56′ 14″	Log.	135573		
Complement of the altitude of the comet	56° 24′ 0″	Log.	18282 *A.*		
		Log.	153855	12° 23′ 51″	D E, perpendicular.

275

Complement of the altitude of the comet, A D	56° 24′ 0″	Antil.	59169	

[274] set as the calculation above. The page prints the sum of 5° 49′ 18″ and 13° 19′ 10″ as 19° 8′ 24″; the two figures add to 19° 8′ 28″, and the half printed beneath, 9° 34′ 14″, is the half of 19° 8′ 28″.

[275] set as the calculation above; the calculation runs on overleaf.

Perpendicular D E	12° 23′ 51″	Antil.	2359 *S.*		
A E		Antil.	56810	55° 29′ 12″	A E
		Complement of the altitude of the comet		56° 24′ 0″	A C
		Difference		54′ 48″	E C
Side E C	0° 54′ 48″	Log.	413892 +	Subtract cossically.	
Perpendicular D E	12° 23′ 51″	Mesol.	151496 +		
Of the angle D C A		Mesol.	262396 —	85° 50′ 29″	D C A
				59° 58′ 4″	B C A
				25° 52′ 25″	D C B

276

4. For the first prosthaphaeresis of inclination.

Parallax reduced to the vertical	0° 15′ 51″	Logar.	537916	
Angle of inclination D C B	25° 52′ 25″	Logar.	82922 *A.*	
There results the prosthaphaeresis of inclination, B I		Logar.	620838	6′ 55″ *Add.*
			Parallax reduced to the vertical	15′ 51″
Therefore the vertical parallax, first equated, becomes				22′ 46″

277

Lastly, we shall also see whether the second prosthaphaeresis, B D, differs much from this first prosthaphaeresis, B I.

5. For finding the second prosthaphaeresis of inclination. Add.

[276] the calculation of step 3 continues here from the previous page, set unruled, in the page's own columns: italic labels, roman figures and point-letters; short rules stand under the figures that are added or subtracted. The degree, minute and second marks are printed only over some rows; the others stand bare on the page, and the marks are supplied here in the house form. The Difference row prints "54 48" with no degree figure, under the minutes and seconds; it is given here as 54′ 48″, with no degree figure supplied, while the next row prints "0 54 48" and is given 0° 54′ 48″. The tag *S.* and the signs + and — are the page's own and are not expanded on the page.

[277] set as the calculation above.

1.	Hypotenuse C B, distance of the comet and the Heel	13° 19′ 10″	Logar.	146802 *S.*		
	Perpendicular D E	12° 23′ 51″	Logar.	153855		
	Of the angle C B D, or H B C		Logar.	7053	68° 44′	C B D
2.	Hypotenuse C B, distance of the comet and the Heel	13° 19′ 10″	Logar.	146802		
	Of the angle of inclination D C B	25° 52′ 28″	Logar.	82922 *A.*		
	Of the perpendicular B I		Logar.	2297245	5° 46′	B I
3.	Hypotenuse C B, distance of the comet and the Heel	13° 19′ 10″	Mesol.	144097 +	Subtract cossically.	
	Perpendicular B I	5° 46′ 0″	Mesol.	229275 +		
	Of the angle C B I		Antilog.	85178 —	64° 44′	C B I
			Angle to be subtracted		68° 44′	D B C
			Angle of inclination sought		4° 0′	I B D
4.	First prosthaphaeresis of inclination, B I	0° 6′ 55″	Mesol.	620838		
	Of the angle I B D, found	4° 0′ 0″	Antil.	244 *S.*		
	Second prosthaphaeresis of inclination, B D		Mesol.	6205946	6′ 56″	*A.*
			Parallax reduced to the vertical		15′ 51″	
			Therefore the true vertical parallax, equated a second time, is		22′ 47″	

[278]

You see, therefore, that this later prosthaphaeresis, B D, is greater by scarcely a single second; and — what very often happens — that the two are altogether equal to each other, especially when the angle D C A, or C D A, which is equal to it, is fairly large and nearly a right angle, as in this example, where it is given as about 85 degrees. And then B I is almost the same as B D, and that later equation does not change the parallax at all.

[Margin: Denuò alio calculo parallaxis ad diem 23Decemb. ſupputetur.] *Let the parallax for December 23 be computed again by another calculation.*

But since this genuine vertical parallax, equated a second time, exceeds those derived from the first and second calculations by one minute or another, we have proposed again, from other distances, namely those of the comet and Algol, observing, how- ever, the same earlier observations, to investigate the

[278] set as the calculation above; the part figures 1–4 stand at the left. The page prints the perpendicular B I bare, as "5 46" in part 2, under the "68° 44′" of part 1, and as "5 46 0" in part 3, under the degrees, minutes and seconds of "13 19 10"; the marks are supplied here by those columns.

parallax, so that by this means we may be made more certain of the true parallax of this 23rd day.

In this inquiry, moreover, it comes to our aid that there is now no need to investigate the earlier distance of the comet and Algol, since it was already obtained above; and also that in the reduction to the orbit only the later distance has to be limited. We could, indeed, omit even that altogether, given that the star Algol is very close to the orbit, so much so that it can introduce no difference: as you will clearly see for yourself, it produces, namely, scarcely two seconds. Furthermore, in the reduction to the vertical we shall likewise enjoy the earlier short cut, and in the whole calculation the same diagrams as in the second investigation.

Investigation of Parallax IV, Computed from the Distances of the Comet and Algol, for December 23 [Inveſtigatio Parallaxeos I V. Ex diſtantiis Cometæ & Algol ſupputatis. Ad diem 23 Decembr.]

Observation 1, at $7^h\ 22^m\ 7^s$ in the evening	Altitude of the comet	44° 28′	Azimuth	48° 19′ east
Observation 2, at $1^h\ 27^m\ 30^s$ in the morning	Altitude of the comet	33° 36′	Azimuth	75° 9′ west

For the later distance.

			Parallax reduced to the vertical		13′ 47″	
			The true vertical parallax, equated a second time		17′ 23″	

For the altitude of the comet of 44° 28′, on December 23, at 7^h 22^m 7^s in the evening.[286]

[Margin: Vnde difcrepantia calculi exorta ſit, & quinam calculus præferendus.] *Where the discrepancy in the calculation arose from, and which calculation is to be preferred.*

It is therefore clear that this parallax is somewhat smaller than the one found in the preceding calculation, although it was computed for the same time and the same altitude, from the same observations and by the same method. Meanwhile, however, I prefer this parallax to the one sought from the distances of the Heel: not only because it agrees better with the parallaxes found in the first and second investigations, but also for this reason, that the star Algol was far closer to the comet's orbit than the Heel was.

[Margin: Declinationes Fixarum nondum omnibus numeris ſunt determinatæ.] *The declinations of the fixed stars have not yet been determined in every respect.*

[286] set as the calculation above; the part figures 1–4 stand at the left. The perpendicular B I is printed bare as "6 4 41" in parts 2 and 3, under the degrees, minutes and seconds of the rows above, and is given 6° 4′ 41″ by those columns. In part 4 the first prosthaphaeresis is printed "3 32" with no degree figure, under the minutes and seconds, and none is supplied. The signs + are the page's own. The italic line beneath the calculation begins "Ad alti-" at the end of its last row and runs on into the line below.

Moreover, it is certain that some slight difference can easily intrude here, on account of the declinations and right ascensions belonging to the different fixed stars. For I have no doubt that the declinations and right ascensions of all fixed stars whatsoever, and especially of the smallest, have not been observed equally well and accurately, even by Tycho himself (which, however, I would say with all respect to the reputation of so great a man). You too will gladly agree with me on this, if you weigh properly whatever we have noted at length about the declinations of the fixed stars in our *Machina*, soon to be published: namely, that the declinations even of the stars of the first rank have not all been duly determined by Tycho, but still need some correction. The table of the declinations and longitudes of the fixed stars by the most learned Riccioli, inserted near the end of Book VI, Chapter XIV, bears witness to this.

[Margin: AtteſtanteRi[?]ciolo.] *On the testimony of Riccioli [?].*

[Margin: Dato aliquo vitio in declinatione Fixarum datur etiam in ſupputatione parallaxium.] *Given some fault in the declination of the fixed stars, there is one also in the computation of the parallaxes.*

Given, therefore, some slight fault in the declination of this or that fixed star, there is one likewise in the longitude and latitude; and consequently, from this source too, by several seconds, indeed sometimes by a whole minute and more, in this or that compu- tation of the parallax from the distances of this or that fixed star and the comet, it is very easy to go astray; so that it is almost impossible, in every investigation, always to derive the parallaxes to the very same seconds from the distances of any fixed stars whatever, even from exactly the same observations.

[Margin: Quibus inſuper de cauſis differentiola aliquot ſecundorum calculo ſe ſe ingerere poſſit.] *For what further reasons a slight difference of several seconds may intrude into the calculation.*

In addition, mathematicians mostly use logarithms to 5 figures; and there it can very easily happen, especially in those monstrous triangles, that here and there we either lose or gain several seconds, which afterwards, in the course of the calculation, either decrease or increase. So it is no wonder that, when some appreciable parallax is given, that difference can extend to one minute or another. To say nothing of the case where still other obstacles arise concerning the positions of the distances: for example, where the parallaxes are somewhat opposed to each other and conflict. About these, and some other precautions to be observed with the greatest care in undertaking the calculation of parallaxes from distances, we shall shortly add more, as this occasion offers.

[Margin: Quòd adeò præciſè parallaxes congruant, demirandum eſt.] *That the parallaxes agree so precisely is to be wondered at.*

There is therefore no reason for you to wonder that some slight difference sometimes arises between these same parallaxes; nor is there reason, on that account, either to accuse the calculator of negligence or to ascribe it to the method of computing. Rather, what is truly to be wondered at is that parallaxes derived from such various and diverse observations, altitudes and azimuths,

from distances both observed and computed, by a different method and a most extensive calculation, still agree with one another so precisely.

But before we pass on to the fifth investigation, I shall give you, as I just promised, certain remarks: namely, which observations and distances should be chosen in order to examine the parallaxes the more accurately. For it is not a matter of indifference whether one submits the distance of this fixed star or that to the calculation of parallaxes; and this not only for the reasons brought forward here and there in the preceding pages, but above all for the following ones, which, on my advice, a careful calculator must always attend to most closely.

[Margin: Animadverſiones quædam ſelectæ, circa calculum ex diſtantiis ſuſcipiendum maximè notabiles.] *Certain selected remarks, most worth noting, on undertaking the calculation from distances.*

1. When the comet is higher in the earlier, vertical observation than in the later, parallel observation — that is, when the comet is continually ascending from the first observation up to the second — it is better and safer to use the distances of those fixed stars which the comet is then approaching. The reason is that at the time when the comet is lower in the first, vertical observation, where that distance is always greater, and again higher in the second, parallel observation, where this distance is always smaller, the comet can never corrupt the true and apparent distance less; especially if, about the parallel distance, the comet stood somewhat lower than the fixed star.
2. But those distances should count for less with you, with the comet in the same position described, when the comet is receding. For then the parallaxes are carried in the opposite direction: namely when, in the earlier, vertical observation, at a smaller distance, the comet is lower, and conversely, in the later, parallel observation, at a greater distance, the comet is higher; especially if, in addition, the comet was much higher than the fixed star in the later, parallel observation.

From this it follows that when sometimes, for lack of observations and distances, or on account of a less convenient position of the comet, such distances as are actually wanted are not available for the calculation, then — even granting that the computation of the parallax is set up for the same time and from the same longitudes and latitudes of the comet — it is altogether impossible for the parallaxes to agree to the very seconds, and indeed sometimes even within one minute or another, from whatever distances are assumed: whether greater or smaller; whether the comet is approaching or receding; whether the fixed star lies under the orbit itself and in the same vertical, or far from the orbit and in different verticals; likewise, in the parallel distance, whether the comet was higher or lower than the fixed star; and no less from the same distances taken perpendicular to the comet and its orbit, whether in the earlier, roughly perpendicular distance the comet is approaching or receding; and again, in the later one, with the comet placed either higher or lower, both with respect to

itself and to the fixed star. In all such widely different configurations of the comet, I say, a slight difference can sometimes arise — namely, when we rely on less suitable distances.

[Margin: Niſi convenientes obſervationes & diſtātias pro eruendis parallaxibus adhibeas, negotium vix pro voto ſuccedit.] *Unless you employ suitable observations and distances for deriving the parallaxes, the business hardly succeeds as one would wish.*

Yet this method of deriving parallaxes is so far from being of less value than the others that, in my judgement at least, it should rather be held far more precious, since this method attends to everything so accurately that it at once registers even the smallest things that occur. For that reason everyone who undertakes this parallactic labour certainly has cause to observe the more accurately each and every point I have remarked, whether now or elsewhere. And if some slight difference shows itself in the seconds, or in some minute, he should not at once spurn the whole business and dismiss it as worthless, as the Peripatetics mostly do in celestial matters (for they reject a thing before they rightly understand it). Rather, he should learn from these points where that slight difference originates; likewise, which distances and observations are more to be trusted; what kind of distances and observations should be chosen for the calculation in preference to the rest; and which parallaxes are the truest of all those derived.

[Margin: Modus noſter eliciendi parallaxes neutiquam a pernandus.] *Our method of deriving parallaxes is by no means to be spurned.*

[Margin: Quare & quando nihil interſit an parallaxis aliquot minutis minor vel major ſit ?] *Why and when it makes no difference whether a parallax is smaller or greater by a few minutes.*

Finally, I add that it makes no difference whether some horizontal parallax is greater or smaller by 3, 4 or 6 minutes, so long as the horizontal parallax does not exceed a whole degree — to say nothing of the case where it is far smaller. For on that account the comet will not suddenly be placed either below or above the Moon. Riccioli agrees with us here, as can be seen in Book VIII, Section I, on comets, page 72 of Volume II of the *Almagestum*: *"Secondly, I ask that it not be put down to captious or sophistical inquiry — as though we were looking for knots in a bulrush — if we require that degree of subtlety in determining the parallax which is necessary for the evidence described above; for although, in the parallax itself, once it is established that it is many minutes greater or smaller than the lunar parallax, a difference of one minute or another harms neither party* (that is, neither those who hold the comet to be ethereal nor those who hold it to be aerial)."

[Margin: Quintâ Inveſtigatione demonſtratur ritè deducta eſſe omnia.] *By a fifth investigation it is shown that everything has been duly derived.*

So that even less ground for doubt may remain about this parallax of December 23 — that it really was by no means greater than we have just computed — here, finally, is its fifth investigation: from exactly the same observations,

both vertical and parallel, namely at $7^h\ 22^m\ 7^s$ in the evening and $1^h\ 27^m\ 30^s$ in the morning, but sought from entirely different distances, namely those of the comet and Palilicium. And this, not only for the reason that, in the earlier observation, that fixed star likewise stood almost in the same vertical as the comet, so that conversely in the la- ter observation it lay almost even more parallel to the horizon than the Heel and Algol; but also because the comet was receding with respect to this fixed star, just as it was approaching the preceding ones, and because Palilicium was somewhat farther from the orbit and had a southern latitude. Since the configuration of the comet and the fixed star was thus entirely different — indeed, on the opposite side — it will be all the more clearly evident, in computing the parallax, whether any error was committed in the preceding investigations. But if from these distances too there comes out exactly the same parallax, equal to those computed before, then it is quite certain that the parallaxes for this day, December 23, have been derived most exactly.

Investigation of Parallax V, from the Distances of the Comet and Palilicium, Computed for December 23 [Inveſtigatio Parallaxeos V. Ex diſtantiis Cometæ & Palilicii ſupp. ad diem 23 Decemb.]

Observation 1, at $7^h\ 22^m\ 7^s$ in the evening	Altitude of the comet	44° 28′	Azimuth 48° 19′ east	vertical

			6° 29′ 20″	Earlier distance of the comet and Palilicium			
Difference of the distances			1° 10′ 10″	or the fictitious apparent motion			

287

[Margin: Motus visus fictus.] *Fictitious apparent motion.*

Before we go further, however, we must first correct the distances found — that is, the apparent motion — by first investigating the distance of Palilicium from the orbit, from the accompanying figure D d. This distance was very considerable in relation to the distances of both bodies, and as a result, as you will see, the apparent motion will be increased not a little. Yet in this example it will come out smaller than the true motion, even though parallax is present in the observations, in accordance with the fifth axiom given above on page 180.

Longitude of Palilicium	64° 57′ 8″

- Occidens. (inside the circle, below the horizon): west
- E. (below): the figure's mark

[291] set as the calculation above; a short rule stands under "24 S.". The first row carries the minute and second marks; in the others the marks are supplied in the house form. The third row prints "14 20" with no degree figure, under the minutes and seconds of the first row, and none is supplied.

• Autor fculps. (lower right): the author engraved it

1. For finding the altitude of Palilicium at $1^h\ 27^m\ 30^s$ in the morning.

Right ascension of the Sun			273° 15′ 54″			
Elongation from the meridian			21° 52′ 30″			
Right ascension of the midheaven			295° 8′ 24″			
Right ascension of Palilicium			64° 1′ 45″			
			231° 6′ 39″			
Excess over 180, the distance from the meridian			51° 6′ 39″	Logar.	25056	
Declination of Palilicium			15° 46′ 12″	Antilog.	3837 *A.*	
Logar. of the declination	B R	130278		B F Logar.	28893	48° 30′ 35″
Antil. of the perpendicular	B F	41176 *S.*		B F Antil.	41176	
Antil.	S F	89102	65° 46′ 48″			
Complement of the elevation of the pole	S A		35° 37′ 0″ *S.*			
	A F		30° 9′ 48″	Antil.	14550 *A.*	
				B K Logarithm	55726	34° 56′ 39″ Altitude of Palilicium
						33° 36′ 0″ Altitude of the comet
				Difference of the altitudes		1° 20′ 39″

292

[Margin: Altitudo Palilicii ad hor. 1 27 min. 30 Sec.] *The altitude of Palilicium at $1^h\ 27^m\ 30^s$.*

Since, therefore, the difference of the altitudes is very slight, the prosthaphaeresis of inclination will accordingly also come out small; and in this case it is, conversely, additive, according to our fifth axiom of prosthaphaereses.

2. To compute the angle B A C.

Complement of the altitude of the comet, C A	56° 24′ 0″	Loga-rithm.	18282

[292] set unruled, in the page's own columns: italic labels, roman figures and point-letters; short rules stand under the figures that are added or subtracted. The degree, minute and second marks are printed only over some rows; the others stand bare on the page, and the marks are supplied here in the house form; no figure is supplied. The tags *A.* and *S.* are the page's own and are not expanded on the page; the *S.* after 35° 37′ 0″ is printed there. The heading of step 1 is set roman, centred, on two lines.

Perpendicular D E		Logarithm.	202408	7° 35′ 30″ D E
Complement of the altitude of the comet	56° 24′ 0″	Antilogarith.	59169	
Perpendicular D E	7° 35′ 30″	Antilogarith.	880 *S.*	
		Antilogarith.	58289	56° 3′ 47″ A E

293 set unruled, in the page's own columns: italic labels, roman figures and point-letters; short rules stand under the figures that are added or subtracted. The degree, minute and second marks are printed only over some rows; the others stand bare on the page, and the marks are supplied here in the house form; no figure is supplied. The tags *Ad.*, *A.* and *S.* are the page's own and are not expanded on the page; the second row prints *Ad.* where the matching row of p. 258 prints *A.* The label of the angle B A C stands on two lines at the right of the last row.

		Complement of the altitude of the comet		56° 24′ 0″	A C
Side E C	20′ 13″	Logarithm.	513605 +	20′ 13″	E C
Perpendicular D E	7° 35′ 30″	Mesologar.	201530 +		
Of the angle D C A		Mesologar.	312075 —	87° 28′ 25″	D C A
				77° 19′ 40″	B C A
			Angle of inclination sought	10° 8′ 45″	D C B

294

4. For the first prosthaphaeresis of inclination.

Parallax reduced to the vertical, B C	0° 14′ 20″	Logarithm.	547974		
Angle of inclination, D C B	10° 8′ 45″	Logarithm.	173640 *A.*		
First prosthaphaeresis of inclination, B I		Logarithm.	721614	2′ 32″	*Add.*
			The parallax reduced to the vertical was	14′ 20″	
			Therefore the vertical parallax, first equated	16′ 52″	

295

[Margin: Parallaxis primò coæquata.] *The parallax first equated.*

Now we shall likewise see whether the genuine second prosthaphaeresis also undergoes some change — which, however, I think can hardly happen, since the angles A C D and C D A now approach a right angle, and the first prosthaphaeresis amounts to only about two minutes. Nevertheless, let us test it by calculation.

5. For finding the true prosthaphaeresis of inclination B D, *add.*

1.	Hypotenuse C B, distance of the comet and Palilicium	7° 39′ 30″	Logar. 201541 *S.*	

294 set as the calculation above; the signs + and — are the page's own. The side E C is printed "20 13" in both places, under the minutes and seconds of the rows above, with no degree figure, and none is supplied. The side B C is labelled "Later.3.B C", with the figure 3 as printed.

295 set as the calculation above. The first row prints the degree figure "0" with its mark, and it is kept. The last two rows print "14 20" and "16 52" with no degree figure, and none is supplied.

	Perpendicular C H, or D E		7° 35′ 30″	Logar. 202408	
	Of the angle H B C, or C B D			Logar. 867	82° 28′ D B C

296

	Of the angle of inclination D C B	10° 8′ 45″	Logar.	173640 *A.*	
	Of the perpendicular B I		Logar.	375181	1° 21′ B I
3.	Hypotenuse C B, distance of the comet and Palilicium	7° 39′ 30″	Mesol.	200644 + *Subt. Cos.*	
	Perpendicular B I	1° 21′ 0″	Mesol.	374794 +	
	Of the angle C B I		Antilog.	174150 +	79° 54′ C B I
			Angle to be subtracted		82° 28′ D B C
			Angle of inclination sought		2° 34′ I B D
4.	Prosthaphaeresis of inclination, first equated	0° 3′ 32″	Mesol.	721614 +	
	Of the angle I B D	2° 34′ 0″	Antil.	100 + *S.*	
	Prosthaphaeresis of inclination B D, second equated		Mesol.	721514 +	2′ 32″ *A.*
			Parallax reduced to the vertical		14′ 20″
			Therefore the genuine vertical parallax, second equated		16′ 52″ exactly as above.
			At the altitude of the comet 44° 28′, on December 23, at 7^{h} 22^{m} 7^{s}.		

297

[296] set as the calculation above; the part figure "1." stands at the left. The angle D B C is printed "82 28" with degree and minute marks and no seconds figure, and none is supplied. The calculation runs on overleaf.

[297] set unruled, in the page's own columns, continuing the calculation of step 5; the part figures "2.", "3.", "4." stand at the left. The degree, minute and second marks are printed only over some rows; the others stand bare on the page, and the marks are supplied here in the house form; no figure is supplied. The fourth part prints the first prosthaphaeresis as "0 3 32", where the preceding page prints it 2′ 32″ beside the same logarithm 721614; the figure is kept as printed. The signs + and the tags *A.*, *S.* and *Subt. Cos.* are the page's own and are not expanded on the page. "exactly as above" renders "planè ut ſuprà", printed on two lines.

[Margin: In hoc calculo, parallaxis ſecunda omninò eſt æqualis primæ.] *In this calculation the second parallax is altogether equal to the first.*

You see, then, that nothing whatever has accrued to the first prosthaphaeresis from this computation; rather, the first and the second prosthaphaeresis have turned out exactly the same, and consequently the parallax second equated is also in every way equal to the parallax first equated. Moreover, it agrees as well as could be with the parallax found by calculations 1 and 4, so that it differs by scarcely a few seconds, although it was sought from such different principles and observations.

Let this be amply sufficient on the parallaxes of the 23rd, derived by this method from the distances; now let us likewise inquire how great the parallaxes of the remaining, following days were. Next, the order would indeed require us to apply the same care to December 24 and 25; but because the sky was very cloudy and observations were lacking, we had to pass over these days and proceed at once to the 26th. Let us see, then, whether the parallax remains of the same size, or whether it gradually, with the passage of time, increases or decreases.

[Margin: Ad diem 26 Decembr. parallaxes inquiruntur ex Cometæ & Palilicii diſtantiis.] *For December 26 the parallaxes are investigated from the distances of the comet and Palilicium.*

For examining the parallaxes of this day, the 26th, we have observations of various kinds: both distances taken with the sextant itself, and others obtained from azimuths and altitudes at very different times. From all of these we shall now examine the parallaxes, sometimes even with one distance observed and the other derived by calculation — something that until now, indeed, was possible only from computed distances alone.

[Margin: An ex diſtantiis omninò æqualibus diverſo tempore captis parallaxis erui poſſit ?] *Whether a parallax can be derived from altogether equal distances taken at different times?*

First there presents itself one distance of the comet and Palilicium, at 9^{h} 0^{m} 34^{s} in the evening, and another a little later, at 10^{h} 13^{m} 30^{s}, which we measured with the sextant — both of exactly the same size, 21° 32′. It is, indeed, an extremely remarkable thing that both turned out of altogether equal size, although the later distance was observed 1^{h} 12^{m} 56^{s} later. Surely the later distance just mentioned ought rightly to have been somewhat greater than the earlier, since the comet was receding with respect to Palilicium. It will therefore seem almost impossible to some how a parallax could be investigated from these entirely equal distances, in which no difference — no mean or fictitious apparent motion — is detected. Yet, in my opinion, it can be done very well. We must not, however, be ignorant of the position in which the comet was seen relative to Palilicium at that time, in each observation.

[Margin: Poſitus Cometæ ad Palilicium.] *The position of the comet relative to Palilicium.*

In the earlier, eastern observation, at $9^h\ 0^m\ 34^s$, near the meridian, the comet stood above Palilicium, though not in one and the same vertical; nor did the vertical coincide exactly with the orbit. In the later, western observation, at $10^h\ 13^m\ 30^s$, the comet was by no means at the same distance from the horizon as the fixed star, but was raised about 12 degrees above Palilicium. Consequently, because of the parallax, which depresses the comet towards the star, the later distance came out somewhat smaller than it really should have been if it had stood at a wholly equal interval either from the horizon or from the vertical point — especially since in the later observation the comet was a little lower than in the earlier one.

But it is clearly established that the comet had a proper motion, such that in the interval of time that elapsed between the two observations, namely $1^h\ 12^m\ 56^s$, it must necessarily have advanced 10′ 57″ further — that is, moved away from the fixed star — as our table of proper motion shows. The later distance should therefore also have exceeded the earlier by altogether that much, namely 10′ 57″. But since this turned out otherwise, and both distances came out of equal size, it is certainly the parallax, depressing the comet towards Palilicium, that makes the later distance smaller by the same amount.

[Margin: Hoc in caſu motus proprius Cometæ eſt ipſa parallaxis media.] *In this case the proper motion of the comet is itself the mean parallax.*

And so, if we consider the matter more deeply, the proper motion itself, 10′ 57″, is here the mean or fictitious parallax; for this proper motion is equivalent to the difference of the distances, or of the apparent and the true motion, as will become rather clearer from the calculation itself. The first part of the calculation is very easy and pleasant, because here the distance of the comet and Palilicium need not be investigated; by contrast, the later part of the calculation will seem the more laborious and tedious, because there the altitudes as well as the azimuths of both the comet and the fixed star have to be computed. The task will therefore involve almost the same labour.

Investigation of Parallax VI, from the Distances of the Comet and Palilicium Taken with the Sextant, for December 26, Evening [Inveſtigatio Parallaxeos V I. Ex diſtantiis Cometæ & Palil.Sextante Captis. Ad diem 26 Decemb. veſp.]

1.	Obser-vation	at $9^h\ 0^m\ 34^s$	Distance of the comet and Palilicium	21° 32′	
2.	Obser-vation	at $10^h\ 13^m\ 30^s$	Distance of the comet and Palilicium	21° 32′	
			Therefore the difference of the distances, or	0	the fictitious apparent motion.

298

[Margin: Quomodo procedendum ſit ubi nulla differentia diſtantiarum datur.] *How to proceed where there is no difference of the distances.*

According to our usual practice, the distances ought now indeed to be reduced to the orbit itself, so as to derive the corrected, or limited, apparent motion. But since both distances are altogether equal in size, and there is no difference between them, this can in no way be done; the matter must therefore be accomplished in an entirely different way. First, this difference of the distances, 0, is to be regarded as if it were — as indeed it really is — the apparent motion of the comet. But in such a configuration relative to the fixed star, namely with the comet above the fixed star and receding from it, this apparent motion is, by axiom 5, smaller than the true motion. Let this apparent motion, 0, therefore be subtracted from the true motion taken from the table, 10′ 57″: the mean or fictitious parallax comes out exactly as great, 10′ 57″. Let us reduce it to the orbit by a new but nonetheless safe method, by means of the angle F I E in the following figure F, or G C E in figure G, and the distance of Palilicium from the orbit; these must therefore be sought first. The distance mentioned above we have indeed already investigated for the 23rd; but to investigate it afresh is neces- sary, because the angle of the orbit and the ecliptic, and also the point of intersection, change little by little from day to day — although the values already found could safely be retained, since the parallax to be derived will be vitiated by almost nothing, at most 1″ or 2″, even if for the 26th you compute both that angle and the point of intersection again most exactly.

1. For finding the distance from the orbit.

Longitude of Palilicium		4° 57′ 8″ ♊			
Point of intersection of the orbit and the ecliptic		28° 31′ 0″ ♉			
Difference G H		6° 26′ 8″	Antilogar.	633	
Latitude of Palilicium, G E		5° 29′ 57″	Antilogar. *A.*	461	
Hypotenuse H E			Antilogar.	1094	8° 27′ 36″
Logar. H E, hypotenuse	191651 *S.*		Logarithm.	191651	
Logar. E G	234516				
Logar. of the angle G H E	42865	40° 38′ 43″			
Angle of the orbit and the ecliptic		73° 57′ 0″			
There remains the angle E H F		33° 18′ 17″	Logarith. *A.*	59949	

[298] set unruled, in the page's own columns; the second line's figures stand bare on the page, and the marks are supplied here in the house form; no figure is supplied. Short rules stand under the second distance.

Of the distance E F	Loga-rith.	251600	4° 38′ 0″ of Palilicium from the orbit

299

[Margin: Diſtantia Palil.ab Orbita.] *The distance of Palilicium from the orbit.*

2. For the angle I F E.

			Angle of the orbit and the vertical	37° 5′ 50″ G C I	in this case.
			Angle of the orbit of the comet and the distance of Palilicium	12° 42′ 52″ E C G	*Add.*
			There results, therefore, the angle sought, E C I	49° 48′ 42″	

[301] set as the calculations above. ”in the following diagram H” renders ”in ſubſeq. Schem. H”, printed on two lines at the right of the seventh and eighth rows.

302

In this way you can, in one operation, reduce the mean parallax, 10′ 57″, both to the orbit and to the vertical — provided, that is, that in our usual way E C is the parallax in the right triangle C E I, and the hypotenuse C I is investigated.

Mesolog. of the side C E, or fictitious parallax	10′ 57″	574923	
Antilog. of the angle E C I	49° 48′ 42″	43805	
		S.	
Mesol. of the parallax reduced to the orbit and the vertical together		531118	16′ 58″

303

[Margin: Parallaxis ad orb. & vertic. reducta.] *The parallax reduced to the orbit and the vertical.*

Diagram. One engraved plate within a plate-mark, across the full measure, holding three figures side by side, marked F, G and H, each set out for one observation; "Autor fculps." (the author engraved it) stands at the lower right of the plate-mark.

Figure F, at the left: three long curved lines descend from A at the top and spread out towards a lower arc running across from G through H, B and C; a further line, labelled "Orbita." (orbit) along its length, crosses them. Small circles mark L and I on the lines; dotted lines run from K to L and from D, past M, to I, K and D standing on the left-hand curve. Below the arc, E stands beside a star at the lower left; straight lines run up from E towards I and L, a dotted line joins E to H, and a dotted line runs from E to F at the foot of a line labelled "Cometæ" (of the comet), the label engraved upside down.

Figure G, in the middle: a circle with A at the top and R to its right; a line from B, outside the circle above, descends through A to C, marked by a small circle, and S stands at the upper left, joined to it by a dotted line. Within the circle, the ecliptic, "Ecliptica.", runs from Q at the left; Palilicium, "Palil." E, is a star on it, with G below; the equator, "Aquator.", runs from M, with H, D and I standing along it; the horizon, "Horizon.", runs from M to L, with K below it. Lines join C to I, to D and to H. "Meridies." (south) and the figure's mark G stand in the lower half; N stands on the right-hand edge, and X at the lower left, where the comet's orbit, "Orbit. Comet.", begins. Beneath the circle: "Hor. 9 0′ 34″ v." ($9^h\ 0^m\ 34^s$, evening).

[302] set unruled, in the page's own columns. The degree, minute and second marks are printed only over some rows; the others stand bare on the page, and the marks are supplied here in the house form; no figure is supplied. A tall printed bracket joins "*add.*" to "in this case" (the page's "hoc loco"). The tags *A.*, *S.*, *add.* and *Add.* are the page's own. The angle G C I is printed "37 5 50", where 32° 19′ 0″ and 4° 56′ 50″ above give 37° 15′ 50″; the sum below, 49° 48′ 42″, follows from 37° 5′ 50″; the figures are kept as printed.

[303] set as the calculation above; the parallax is printed "10 57" and the result "16 58" with minute and second marks and no degree figure, and none is supplied.

Figure H, at the right: a circle with A at the top, F, Q and V on the upper left, S and G on the upper right, P and X on the left, and L at the right end of the horizon, "Horizon.", which runs from M; K and O stand below the horizon. The comet's orbit, "Orbita Cometæ.", runs from C, marked by a small circle, to G; E, B, H, w and D stand close below C, with R and I further down at the left. Dotted lines run from V and from F towards the lines through C, and join B to H and D. Below the horizon stand "Occidens." (west) and the figure's mark H; the equator, "Aquator.", and the ecliptic, "Ecliptica.", descend to the right, to T and N on the circle. Beneath the circle: "Hor.10 13′ 30″ V." ($10^h\ 13^m\ 30^s$, evening).

- Figure F: A, "Orbita.", F (figure mark), K, L, D, M, I, G, H, B, C, E, F, "Cometæ".
- Figure G: S, B, A, R, C, "Ecliptica.", "Palil.", E, G, I, D, H, "Aquator." (equator), "Horizon.", Q, M, L, K, "Meridies.", G (figure mark), N, X, "Orbit. Comet.", "Hor. 9 0′ 34″ v.".
- Figure H: A, F, Q, S, G, V, P, E, C, "Orbita Cometæ.", B, H, w, D, R, I, X, M, L, K, O, "Horizon.", "Occidens.", H (figure mark), "Aquator.", "Ecliptica.", T, N, "Hor.10 13′ 30″ V.".
- "Autor ſculps." at the lower right.

Moreover, now that the parallax has thus been reduced to the orbit, it must now also be limited in the western quadrant, by investigating its prosthaphaeresis of inclination, since the comet stood much higher than Palilicium. Before this can be done, however, we must have ready to hand the altitudes of the comet and of the fixed star for the time of the later observation, $10^h\ 13^m\ 30^s$. Let us therefore now go and seek them.

For finding the altitude of the comet.				For finding the altitude of Palilicium.

305

[Margin: Hocce in exemplo Proſtha. inclinat. ſubtractiva eſt.] *In this example the prosthaphaeresis of inclination is subtractive.*

Since, therefore, the comet is much higher than Palilicium, a quite considerable prosthaphaeresis of inclination will certainly result — and, according to the fifth axiom, a subtractive one.

For the angle B A C.

[304] two calculations set side by side, the comet's at the left and Palilicium's at the right, each under its own heading; the label of Palilicium's right ascension stands in the middle of the line, before its figures. The degree, minute and second marks are printed only over the first row of figures; the others stand bare on the page, and the marks are supplied here in the house form; no figure is supplied. In both columns the right ascension of the midheaven is printed 69 52 18, where 276° 30′ 18″ and 153° 22′ 30″, less 360°, give 69° 52′ 48″; the differences below follow from 69° 52′ 18″; the figures are kept as printed. In Palilicium's logarithm of the distance from the meridian one figure is not settled between 3 and 8, marked [?].

[305] two calculations set side by side, the comet's at the left and Palilicium's at the right, continuing the pair begun at the foot of the previous page. The degree, minute and second marks are printed only over the third row; the others stand bare on the page, and the marks are supplied here in the house form; no figure is supplied. The tags *A.* and *S.* are the page's own.

Complement of the altitude of the comet, C A	27° 2′ 0″	Log.	78854	
Complement of the altitude of Palilicium, B A	38° 52′ 43″	Log.	46573 *A.*	
Difference of the distances	11° 50′ 43″	Log.	125427	Earlier aggregate.
Distance of the comet and Palilicium, B C	21° 32′ 0″			
Sum	33° 22′ 43″

				43° 41′ 8″ A B C
		The angle of inclination sought		32° 58′ 8″ D B C

[306] set unruled, in the page's own columns; the heading is printed without a step number. The marks are printed only over the first row and over the half-angle; the rest are supplied in the house form; no figure is supplied.

307

4. For the first prosthaphaeresis of inclination.

Parallax reduced to the vertical, B C	16′ 58″	Loga-rithm.	531118	
Angle of inclination, D B C	32° 58′ 8″	Loga-rithm.	60847 *A.*	
First prosthaphaeresis of inclination, C W		Loga-rithm.	591965	9′ 14″ *Subt.*
The parallax reduced to the vertical was				16′ 58″
Therefore the vertical parallax, first equated				7′ 44″

308

[Margin: Parallaxis primò coæquata verticalis.] *The vertical parallax, first equated.*

5. For finding the second prosthaphaeresis of inclination, in this case subtractive.

1	Hypotenuse C B, distance of the comet and Palilicium	21° 32′ 0″	Logar.	100228 *S.*	
	Perpendicular D E or B H	20° 29′ 38″	Logar.	104952	
	Angle B C D, or B C H		Logar.	4724	72° 32′ 0″ D C B.
2	Hypotenuse C B, distance of the comet and Palilicium	21° 32′ 0″	Logar.	100228	
	Angle of inclination D B C	32° 58′ 8″	Logar.	60847 *A.*	
	Perpendicular C W		Logar.	161075	11° 31′ 0″ C W
3	Hypotenuse C B, distance of the comet and Palilicium	21° 32′ 0″	Mesol.	92993 + *S.* cossically	
	Perpendicular C W	11° 31′ 0″	Mesol.	159083 +	
	Angle sought, B C W		Antil.	66090 +	58° 54′ 0″ B C W
					72° 32′ 0″ B C D
			The angle of inclination sought		13° 38′ 0″ W C D

[307] set as the calculation above. The marks are printed only over the first row and over 43 41 8; the rest are supplied in the house form; no figure is supplied. The signs + and — after the logarithms are the page's own. In the row for the perpendicular D E at the right, the first figure of the seconds is an under-inked sort, read 3 (probable; a second copy would confirm); the same quantity is printed 20 29 38 at the left two rows below. The angle D B A is printed 76 93 16, a minutes figure above 60; 43° 41′ 8″ and 32° 58′ 8″ give 76° 39′ 16″; the figure is kept as printed.

[308] set as the calculations above; the marks are printed over 16 58 and 9 14 only, the rest supplied in the house form; the last two values are printed without a degree figure, and none is supplied.

4	First prosthaphaeresis of inclination, C W	0° 9′ 14″	Mesol.	591965 +	
	Angle of inclination W C D	13° 38′ 0″	Antil.	7858 +	
	Second prosthaphaeresis of inclination, C D		Mesol.	584107 +	9′ 59″ *Subtrah.*
	The parallax reduced to the vertical was				16′ 58″
	Therefore the genuine vertical parallax, equated a second time				6′ 59″

For the altitude 67° 26′ at $9^h\ 0^m\ 34^s$, observed on December 26.[309]

The calculation therefore shows clearly that the parallax of this day, the 26th, is somewhat smaller than that of the 23rd. Whether this is really so or not, let us inquire by a further, different investigation: namely with the same earlier distance of the comet and Palilicium, observed with the sextant at $9^h\ 0^m\ 34^s$, but with another added in place of the later one, which is to be computed from the altitude and azimuth observed at $11^h\ 38^m\ 22^s$. In this way we shall not always rely on the same distances and the same observations, and the matter will be made clearer to everyone. The later distance must therefore first be investigated from the longitudes and latitudes, as we have been accustomed to do.

[Margin: Parallaxis diei 26 minor eſt illâ ad diem 23 inventâ.] *The parallax of the 26th is smaller than that found for the 23rd.*

Investigation of Parallax VII, from the Distances of the Comet and Palilicium, One Observed and the Other Sought by Calculation, for December 26, Evening [Inveſtigatio Parallaxeos VII. Ex diſtantiis Cometæ & Palilicii, alterâ obſervatâ, alterâ ex calculo, quæſitâ. Ad diem 26 Decemb. veſp.]

1. Observation at $9^h\ 0^m\ 34^s$. Observed distance of the comet and Palilicium 21° 32′, east.
2. Observation at $11^h\ 38^m\ 22^s$. Altitude of the comet 52° 36′ 30″; azimuth 71° 22′, west.

Longitude of the comet at the later observation	24° 33′ 33″	Latitude of the comet, C L	13° 41′ 27″ north	Latitude of Palilicium	5° 29′ 57″ south
Longitude of Palilicium	4° 57′ 8″	Complement, A L	76° 18′ 33″	Distance from the pole	95° 29′ 57″ A

[309] set unruled, in the page's own columns, with the part figures 1–4 at the left as printed. The marks are printed only over the first row, over 72 32 0 and over 9 59; the rest are supplied in the house form; the last three values are printed without a degree figure, and none is supplied; the first prosthaphaeresis is printed with a leading 0, as kept. The signs + are the page's own. The closing words "Ad altitudinem … obſerv." are printed after the last value and run onto a second line.

For the first prosthaphaeresis of inclination.

Parallax reduced to the vertical, B C	0° 11′ 3″	Logar.	573978	
Angle of inclination D B C	17° 32′ 39″	Logar.	119921 *A.*	
There results the first prosthaphaeresis of inclination, C W		Logar.	693899	3′ 20″ *Subt.*
The parallax reduced to the vertical was				11′ 3″
Therefore the vertical parallax, first equated				7′ 43″

[315] set unruled, in the page's own columns; the heading is printed without a step number. The marks are printed only over the first row and over 60 42 50; the rest are supplied in the house form; no figure is supplied. The second complement, beside A D, is labelled for the comet on the page, where the next row labels the same figure for Palilicium; both labels are kept as printed. The signs + and — are the page's own. The angle B A C is printed 32 12 46 here, where the previous page prints 22 12 46 and its half-angle 16° 16′ 23″ would give 32° 32′ 46″; the figures are kept as printed.

316

[Margin: Parallaxis primò coæquata.] *The parallax first equated.*

Although, in my judgment at least, the second prosthaphaeresis of inclination changes the parallax found only very slightly, let us nevertheless set out the whole calculation, so that you may see this properly for yourself.

For investigating the genuine prosthaphaeresis of inclination, B D, in this case to be subtracted.

1.	Hypotenuse C B, distance of the comet and Palilicium	21° 47′ 10″	Logar.	99117 *S.*	
	Perpendicular D E, that is B H	21° 42′ 53″	Logar.	99430	
	Of the angle B C D, or B C H		Logar.	313	85° 28′ 0″ B C D
2.	Hypotenuse C B of the comet and Palilicium	21° 47′ 10″	Logar.	99117	
	Of the angle of inclination D B C	17° 32′ 39″	Logar.	119921 *A.*	
	Of the perpendicular C W		Logar.	219038	6° 25′ 0″ C W
3.	Hypotenuse C B of the comet and Palilicium	21° 47′ 10″	Mesol.	91721 + *Subt.* cossically	
	Perpendicular C W	6° 25′ 0″	Mesol.	218514 +	
	Of the angle sought, B C W		Antilog.	126793 +	73° 39′ 0″ B C W
					85° 28′ 0″ B C D
			The angle of inclination sought		11° 49′ 0″
4.	First prosthaphaeresis of inclination, C W	0° 3′ 20″	Mesol.	693899 +	
	Of the angle W C D	11° 49′ 0″	Antil.	2142 + *S.*	
	Second prosthaphaeresis of inclination, C D		Mesol.	691757 +	3′ 24″ *S.*
	The parallax reduced to the vertical was				11′ 3″
	Therefore the vertical parallax, equated a second time, is only				7′ 39″

317

[316] set as the calculation above; the parallax is printed with a leading 0, kept; the last three values are printed without a degree figure, and none is supplied.

[317] set as the calculations above, with the part figures 1.–4. at the left as printed. The marks are printed only over the first row, over 85 28 0, over 6 25 0, over 3 24 and over the closing 4; the rest are supplied in the house form; the last three values are printed without a degree figure, and none is supplied; the first prosthaphaeresis is printed with a leading 0, kept. The signs + are the page's own.

— barely 4″ smaller than the earlier, first-equated parallax; namely for December 26 at 9^h 0^m 34^s in the evening, with the comet at an altitude of 67° 26′ 0″.[318]

[Margin: Genuina parallaxis verticalis ad d. 26.Dec.] *The genuine vertical parallax for December 26.*

However well this parallax agrees with the earlier one, which was found in the preceding computation from different observations for the same altitude, let us nonetheless go further and investigate it once more for this same day, December 26, from entirely different observations, so that we may not seem to have rested content with only two examples.

Just as not each and every observation can be used for this calculation, for the various reasons given earlier, so now too we must take care not to stumble in this part as well. In turn, we shall indeed keep the same earlier observation at 9^h 0^m 34^s, as we shall also in the following investigations for this day, since we have no other at hand that could be substituted in its place; for the other, however, we shall take an entirely different one, made on December 27 at 2^h 6^m 0^s in the morning. At that time, in each of the two observations, two distances of the comet and Palilicium were indeed accurately observed with the sextant; but I think the business will not succeed so happily from these. For in these same distances the parallaxes are carried in opposite directions, and moreover Palilicium, in neither of the distances, stands precisely under one and the same vertical as the comet, nor is either distance sufficiently parallel to the horizon; so that, for that reason, the apparent motion comes out smaller than the true one. It is better, therefore, to reject these distances of the comet and Palilicium, since they are less suited to finding parallaxes, and to substitute others in their place from which the parallaxes can be derived more precisely.

[Margin: Etiamſi aliqua diſtantia obſervata,calculo non conveniat, non ideò tamen ipſa obſervatio illicò rejicienda.] *Even if some observed distance does not agree with the calculation, the observation itself is not on that account to be rejected at once.*

Yet there is no reason why, on that account, we should altogether discard those observations made at that very time, since other distances can be computed from them which will suit our purpose exceedingly well: namely, if from the longitudes and latitudes themselves (derived, that is, from those distances of the comet and Palilicium) we work out the distances of the comet and the Bright Star of Aries. For this star stood, not near the orbit, as has been the case so far, but at roughly a right angle to the orbit and the comet; so much so that in the first, eastern observation, at 9^h 0^m 34^s, the distance of the comet and the Bright Star of Aries was roughly parallel to the horizon, while in the second, later, western observation, at 2^h 6^m 0^s in the morning, it was nearly vertical. Although this configuration of the phenomenon may seem wholly foreign to that of the preceding observations, and almost the opposite of it, the parallaxes

[318] the page prints the time as 9 0° 34″, with a degree mark over the 0.

are nonetheless found from similar observations just as well, indeed even more accurately, provided the calculation is properly undertaken. How it ought to be set up correctly we shall show plainly in the following investigation. But you must give it your close attention here. For this is the first example of its kind that we are about to bring forward, one in which both the method of the equation or of the limitation and the procedure are, in many respects, altogether very different; and at the same time wholly new axioms must also be set out, both with regard to the distances (from which, that is, we are to foresee the parallaxes) and with regard to the prosthaphaereses of inclination, which in observations of this kind take on an entirely different and changing nature. Therefore, if you take delight in these subtler speculations of Urania, and are also anxious to perceive and penetrate everything properly, you certainly have reason to weigh each point more deeply and more exactly: perhaps you will not regret the labour.

[Margin: Ex contrariâ prorsùs phænomeni conſtitutione æq́; accuratè parallaxes inveſtigantur.] *From a wholly opposite configuration of the phenomenon the parallaxes are investigated just as accurately.*

[Margin: In hujusmodi operationibus diverſa planè à priori æquationis & limitationis ratio eſt adhibend.i, diverſisq́ue axiomatibus opus eſt.] *In operations of this kind a method of equation and of limitation altogether different from the earlier one must be applied, and different axioms are needed.*

First, however, let the distances be computed by the usual method, with the help of the following delineation I. In it, as you see, the arrangement of the lines is very different: for E, the Bright Star of Aries, views the comet and its orbit at nearly a right angle, and stands quite far from the orbit. Nevertheless it enjoys nearly the same triangles for unravelling the equation of the distances, as you will learn more fully from the calculation itself.

Investigation of Parallax VIII, from the Distances of the Comet and the Bright Star of Aries, for December 27 [Inveſtigatio Parallaxeos VIII. Ex diſtantiis Cometæ & Lucidæ Arietis, ad diem 27 Decemb.]

1	Observation at $9^h\ 0^m\ 34^s$ in the evening	Altitude of the comet 67° 26′	Parallax
2	Observation at $2^h\ 6^m\ 0^s$ in the morning	Altitude of the comet 31° 12′	vertical

319

[319] the words "Parall." and "Vertic." stand one above the other at the right of the two lines, so that read downward they give "vertical parallax"; no value stands beside them. The marks are printed only in the first line; the second line's are supplied in the house form.

Longitude of the comet, 1st observation	24° 35′ 30″ ♉	Latitude of the comet	13° 24′ 18″ north	Latitude of ♈	9° 57′ 30″ north

321

Diagram. Delineation I, an engraved figure set at the left of the text. A spherical triangle has its apex A at the top. From A a curved line, labelled along its length "Orbita Cometæ" (the orbit of the comet), runs down to the left, with a second curve close beside it. A straight side runs from A down to the right to G on the ecliptic. The large letter I stands in the open field of the triangle. Points on the left-hand curves are marked F, L and I, with M just below L; the right-hand side carries K, D and E; E is marked with a star and labelled "Luc.♈" (the Bright Star of Aries). Dotted lines run across the triangle between the two sides, and solid curves run from L and I to E. At the foot, the ecliptic ("Ecliptica.") passes through H, B, C and G; B and C stand at the feet of two near-vertical lines. "Aut. ſculps." (engraved by the author) stands below the ecliptic at the lower right.

- A (apex, top): A
- along the left curve: Orbita Cometæ (the orbit of the comet)
- field of the triangle: I (the delineation's letter)
- left curves, upper: F
- left curves, middle: L
- left curves, lower: I
- below L: M
- right side, upper: K
- right side, middle: D
- right side, lower: E, with the label Luc.♈ (the Bright Star of Aries)
- ecliptic, left: H
- ecliptic, under I and L: B, C
- ecliptic, right: G
- along the ecliptic: Ecliptica. (the ecliptic)
- lower right: Aut. ſculps. (engraved by the author)

[Margin: Si motus proprius Cometæ non adhæreret, breviori viâ res expediretur.] *If the comet had no proper motion attached to it, the matter would be settled by a shorter route.*

If, in this case, the comet had been entirely free of all proper motion, the matter would already be finished and the parallax itself found, namely from the bare difference of the distances; and that difference would need nothing

[321] set as the calculation above. The marks are printed only over the first row and over 20 48 15, 75 7 23 and 21 21 10; the rest are supplied in the house form; no figure is supplied.

but the vertical reduction and the prosthaphaeresis of inclination to elicit the genuine parallax sought. Now, however, since the comet enjoys a quite fast proper motion, the distances must first be equated with each other, as though no proper motion of the comet had intervened between the distances, so that the parallax of the orbit itself may come out; and this indeed by the fourth way, clearly set out at the beginning of this Book IV, p. 188. For by the true and apparent way (according to the first, second and third methods), with the comet in such a position, the matter is not settled so conveniently. But one must carefully consider which distance ought to be reduced, the earlier or the later, since only one of the two needs correction. In fact

[Margin: Multùm intereſt quænam diſtantia, priorne an poſterior limitanda ſit ?] *It matters a great deal which distance, the earlier or the later, is to be limited.*

however, one ought to limit the distance that is greater in itself (which also suits this operation better), the distance in which the comet, with respect to its proper motion, was truly farther from the fixed star: as in diagram I, the earlier distance I E. For there the comet at I is not only farther from the fixed star E than the comet at L, but also from F, the point of the perpendicular falling from the fixed star onto the orbit. Yet the greater distance is not always farther from F, especially if both distances happen to lie very close to the perpendicular F and the parallax lies hidden in one or the other of them; then, I say, it quite often happens that the smaller distance is in fact farther from F. This, however, can hardly be expressed without a fuller and more extended explanation (which I would gladly avoid here) as well as it can be perceived in practice itself, from a well-constructed figure and a careful investigation; nevertheless, it is very useful to know it properly, if one's intention is to determine the parallax exactly.

So that you may be all the more secure in this business, take the following axiom, but one constructed for those cases where the distances do not lie too close to F, and the perpendicular E F falls not within but outside both distances. When the comet is placed in approach to the fixed star and the perpendicular, the earlier distance (with respect to the observations), since it is the greater and makes the smaller angle with the orbit at the comet, is to be reduced and diminished with respect to the later distance: such is E I, which is the greater and shows the smaller angle E I F, for the angle E I F is smaller than the angle E L F, just as the distance E L is smaller than E I. But when the comet is in recession, from the fixed star as well as from the perpendicular, the later distance is to be limited, since in that case it is likewise the greatest and has the smaller angle.

[Margin: Axioma peculiare pro parallaxibus ad certos caſus.] *A special axiom for parallaxes, for certain cases.*

On this basis, therefore, the earlier distance E I is now to be corrected and stripped of all proper motion. Before this is undertaken, however, let the distance of the Bright Star of ♈ from the orbit, E F, be sought, as usual, and also that smaller angle F I E.

[Margin: Quænam diſtantia corrigenda.] *Which distance is to be corrected.*

For the distance of the fixed star from the orbit of the comet.

Longitude of the Bright Star of ♈		2° 49′ 57″ ♉				
Point of intersection of the orbit and the ecliptic for the 27th		28° 31′ 0″ ♉

	the later distance E L		21° 21′ 10″		
	And you will have the true parallax of the orbit		6′ 1″		

324

[Margin: An aliqua parallaxis obſervationibus ſubſit detegere.] *To detect whether some parallax underlies the observations.*

Before we go any further, however, the reasoning of this calculation advises us to pause a little, so that we may first set out certain general axioms which, unless I am mistaken, apply to any comets whatever. Under their guidance anyone will be free to judge more exactly whether or not some parallax inheres in the observations submitted to calculation; so that, if perhaps no parallax is present in them, you do not undertake and continue the calculation further in vain, but on the contrary deliberately avoid so great a labour. But it must be known in advance, as we have also impressed on you above, that in these cases (unless something prevents it), when the comet is in approach to the fixed star, the earlier distance is always greater than the other, later one; conversely, when the comet is in recession, the later is greater than the other, earlier one; and

[324] set unruled, in the page's own columns. The marks are printed only over the first row and over 48 11, 8 26 and 21 27 11; the rest are supplied in the house form; the parallax is printed "6 1" and the perpendicular and I M without a degree figure, and none is supplied. The figures 10.123, 9.822, 0.301, 7170.000 and 7179.822 are printed with a point, as here. The tags *A.* and *S.* are the page's own.

everyone will see at first glance that the matter really stands so. Yet not rarely we experience the contrary, by reason of the parallax. When, however, and in which cases this happens, no one will be able to miss, from the following 8 axioms. But I always speak (and I should like you to note this well) not of bare distances, but of those of which one or the other has already been limited, and where the proper motion has already been excluded, as was done by us a little earlier.

Axioms, by Whose Help, from Two Distances of a Comet and a Fixed Star, One of Them Corrected and the Other Bare, It Is Safely Detected Whether Some Parallax Underlies the Observations [AXIOMATA. Quorum beneficio, ex duabus Cometæ & Fixæ diſtantiis, alterâ tamen correctâ, alterâ nudâ tutò detegitur, an obſervationibus aliqua ſubſit parallaxis ?]

[Margin: Axiomata generalia notatu digna.] *General axioms worth noting.*

1. When the comet is in approach to a fixed star that is lower, that is, in the later, vertical observation, that said later vertical distance is smaller than the earlier, parallel one: especially if the comet, together with the star, is descending in respect of altitude, or is higher in the earlier, parallel observation than in the later, vertical one, and conversely lower than the fixed star in the earlier, parallel observation, if there is a parallax. But if the said later vertical distance is greater, no parallax at all is to be expected.

[Margin: Axioma primum.] *The first axiom.*

2. The same happens (namely that the later vertical distance is smaller, and the earlier parallel one greater) when the earlier observation, or distance, is vertical, and the later

[Margin: Axioma ſecundum.] *The second axiom.*

parallel, namely when the comet is in approach to a higher star in the vertical observation: especially if, in this said earlier vertical observation, the comet is lower than in the later, parallel one, and then, in this later, parallel one, higher than the fixed star, the true proper motion being moreover not very notable, if some parallax is present.

3. But when we experience the contrary, the comet being in approach to a fixed star that is higher, that is, in the later, vertical observation, that said later vertical distance can sometimes be greater than the earlier, parallel one: especially if the comet, together with the star, is in descent as regards altitude, or if in the earlier, parallel observation the comet is higher than in the later, vertical one, and then, in the earlier, parallel observation, much higher than the fixed star; and further, the proper motion is not very notable, if some parallax lies hidden.

[Margin: Axioma tertium.] *The third axiom.*

4. The same happens when the earlier observation, or distance, is vertical, and the later parallel, the comet being in approach to a lower star in the earlier, vertical observation: especially if both bodies are ascending, or the comet is lower in the earlier observation than in the later, and then the comet is lower

than the fixed star in the later, that is, the parallel, observation, and the true proper motion is not very rapid, if some parallax inheres in the observations.

[Margin: Axioma quartum.] *The fourth axiom.*

5. But when the comet is in recession from a fixed star that is higher in the later, vertical observation, the said later vertical distance is always greater than the earlier, parallel one: especially when the comet and the star are descending in respect of altitude, or when the comet is higher in the earlier, parallel observation than in the later, vertical one, and then, in the earlier, parallel observation, higher than the fixed star, if some parallax underlies them; but if the later vertical distance is smaller, there is no parallax at all.

[Margin: Axioma quintum.] *The fifth axiom.*

6. The same occurs (namely that the later, parallel distance is greater than the earlier, vertical one) when, that is, the earlier observation, or distance, is vertical, and the later parallel, the comet being in recession from a fixed star that is lower in the vertical observation: especially, however, if the comet is lower in the earlier, vertical observation and higher in the later vertical one, or both are ascending, and then the comet, in the later, parallel observation, is lower than the fixed star, if some parallax adheres to the observations.

[Margin: Axioma ſextum.] *The sixth axiom.*

7. But when the contrary happens, the comet being in recession from a fixed star that is lower, that is, in the later, vertical observation, that said later vertical distance can sometimes be smaller than the earlier, parallel one: especially if the comet, in the later, vertical observation, was much lower in altitude than in the earlier, parallel observation; much more so if the comet, in this earlier observation, is higher than the fixed star, and the true proper motion of the comet is not so swift, if a parallax resides in the observations.

[Margin: Axioma ſeptimum.] *The seventh axiom.*

8. The same occurs (namely that the later distance is smaller than that earlier, parallel one) when the earlier observation is vertical, and the later parallel, the comet being in recession from a higher fixed star: especially if the comet, in the earlier, vertical observation, was much lower in altitude than in the earlier, parallel observation, and then, in the later, parallel observation, the comet is higher than the fixed star;

[Margin: Axioma octavum.] *The eighth axiom.*

above all if the true proper motion was slow, if the observations are subject to parallaxes; otherwise they are entirely free of all parallax.

Although these axioms will perhaps seem, at first sight, of slight weight, yet in my judgement, at least, I think a great deal should be attributed to them: not so much because it took art and labour to construct them properly, as because they have a great use with regard to phenomena of every kind; and because, with their help, it is at once clear to anyone whether or not some parallax inheres in the corrected distances, something which otherwise, believe me, would give a great deal of trouble even to those not lightly versed in the science of the stars. Above all, these axioms will be of no small help to those more extended and

most intricate ones handed down earlier, on p. 179, and will shed a remarkable light on them; and the matter will become all the clearer: namely, why the apparent motion is sometimes carried in the contrary direction, although a parallax is present in the observations. Then, too, these will leave you free to distinguish properly between observations and distances, whether observed or computed, and to choose the more certain and more suitable ones; and also to avoid without difficulty those above all in which the apparent motion is driven in the contrary direction, according to axioms 3, 4, 7 and 8. This is not, indeed, for the reason that no parallaxes at all can be drawn from them; but only because from them, sometimes, parallaxes cannot be elicited as accurately, to within a few seconds, indeed even to within one whole minute or two, according to their size, as we can elicit them from those that follow axioms 1, 2, 5 and 6 (in which the apparent motion is always found to be ordered).

[Margin: Axiomata præcedentia, ſicut haud vulgari labore ſunt conſtructa, ſic pariter egregium habent uſum.] *The preceding axioms, just as they were constructed with no ordinary labour, so likewise have an excellent use.*

However much we wished it, we could not always use these ordered distances for drawing out the parallaxes; sometimes, where the others were lacking, we had to rely on those unordered observations as well. Nevertheless, as we have said, hardly any very notable small difference then showed itself. Yet we always attributed more to the ordered ones, as is indeed deservedly their due, and for the most part used those unordered ones only as a supplement.

[Margin: Ordinatis diſtantiis, quando fieri poteſt, inſiſtendum.] *One should rely on ordered distances when it can be done.*

But I return to our calculation, in which the difference of the distances, one of them, that is, corrected and the other bare, came out as 6′ 1″, which now represents the parallax of the orbit. For since, according to our axiom 1, the later vertical distance is smaller than the earlier, parallel distance, a parallax certainly inheres in those distances; and so the calculation must by all means be continued, so that we can derive the genuine vertical parallax, equated a second time. We shall obtain it, moreover, extremely well from this configuration with respect to the Bright Star of Aries, according to the first axiom, and somewhat better than from the following calculation IX, according to axiom 3, for the reasons already stated: there the comet's position with respect to Capella was quite different, although for the same time.

[Margin: Adjecto calculo parallaxis inhæret.] *A parallax inheres in the calculation added.*

This parallax of the orbit, then, found to be 6′ 1″, must now also be reduced to the vertical; and indeed from the later, western observation, since there the comet stood almost under the same vertical as the fixed star; so that in this way the prosthaphaeresis of inclination may afterwards be investigated from the earlier, parallel observation. The prosthaphaeresis of inclination could, however, also have been traced first from the earlier observation and afterwards

reduced to the vertical, provided you note carefully which observation pertains to the vertical reduction;

[Margin: Quo ordine inveſtigatio inſtituenda.] *In what order the investigation is to be undertaken.*

meanwhile, however, since in the preceding examples we have always been accustomed to bring the parallaxes back to the vertical first, let us follow that order further.

This vertical reduction, however, in those examples, namely, in which the fixed stars are set at a right angle to the comet and its orbit (as in this configuration of the Bright Star of Aries, or in the following one of Capella and the comet), is carried out in an entirely different way than if the fixed stars are situated near the orbit itself, that is, at a smaller angle: something that is truly most necessary to observe; otherwise you will go badly astray. For in these cases the parallax is not deduced from the apparent and the true motion, nor estimated in the orbit; it is investigated only from the distances stripped of all proper motion, just as if no proper motion had belonged to the comet. And the matter is taken as if, in one observation, the comet, together with the fixed star, had been parallel to the horizon, where the distance is at once true and apparent; and in the other, as if the comet, together with the star, had stood under about the same vertical, where the parallax necessarily shows itself at once, when, that is, one distance is subtracted from the other. Here, therefore, the parallax is considered in the line of distance E C (Fig. K, following), and by no means in the orbit, as it must be with those fixed stars lying near the orbit.

[Margin: Nota; Quandò Fixæ adCometam ſub normali angulo exiſtunt, reductio ad verticalem aliâ planè viâ tentanda eſt.] *Note: when the fixed stars stand at a right angle to the comet, the reduction to the vertical must be attempted in an entirely different way.*

[Margin: Quænam hujus rei ſit ratio ?] *What the reason for this is.*

But it very rarely happens that the comet C and the fixed star E, or the line of distance E C, stand so exactly under the same vertical, that is, that the distance E C faces the horizon at an exact right angle; usually, as also in this example of ours adjoined, the line of distance of the comet and the fixed star, C E, inclines to the horizon at a certain acute angle. Therefore, since the parallax found for the orbit, or rather the mean parallax, 6′ 1″, is given in this line of distance C E, inclined to the horizon, it certainly follows that this parallax partakes in part of the parallax of longitude and of latitude, and that in the vertical line C D it must necessarily have been somewhat greater. It falls to us now to examine this difference, which arises from the angle of the distance and the vertical, E C D: namely, how great the parallax itself would have appeared in the vertical circle A C D O.

Now let us say in what way this reduction to the vertical is accomplished, namely by seeking the angle E C D in place of that of the vertical and the orbit used for stars near the orbit. 1. For that time of the observation, $2^{h}\ 6^{m}\ 0^{s}$, let both the altitudes and the azimuths of both the comet and the fixed

star be sought, if they are not given by the observation; then the difference of the azimuths, if the comet and the fixed star lie in the same quadrant, or, if not, the complement of each one's azimuth to the quadrant, gives K O, or the angle E A D. 2. In the right-angled triangle E D A, let the perpendicular E D be found from the angle A just found and from A E, the complement of the altitude of the fixed star. 3. In the triangle E D C, right-angled at D, from the perpendicular E D found and the hypotenuse E C, namely the distance of the comet and the fixed star, the angle sought, E C D, becomes known. 4. Transfer the parallax of the orbit found above, 6′ 1 [?], C G, into the line of distance C E, and construct the right-angled triangle C G I, so that C I is the hypotenuse, in the vertical circle A C O; and at the same time you will have from that C I the parallax reduced to the vertical that is sought, which you will find from the angle G C I, or E C D, and from C G, the parallax of the orbit.

[Margin: Quâ ratione parallaxis mixta, ad nudam verticalem redigi debeat.] *In what way a mixed parallax should be reduced to the bare vertical.*

Diagram. Figure K, the left of two engraved circular figures standing side by side at the head of the page, for the observation at $2^{h}\ 6^{m}\ 0^{s}$ in the morning. A circle stands for the sky, with the zenith A at the top and the horizon M L crossing it as a shallow arc. The ecliptic and the equator run as two parallel diagonals down from the upper left. The comet C, drawn as a small circle with a cross, lies on the arc of the comet's path, which runs from C to R on the rim; the star E, the Bright Star of Aries, lies below and to the right of C. Dotted lines run from C towards F, from I towards G, and from D through E towards V. O and K stand on the horizon below D and E, Y on the horizon at the left; the orbit runs up from X at the lower left; N stands on the rim at the bottom.

- A (top of the circle): zenith
- F, S (upper rim, right of A)
- [?] (outside the circle at the upper left, near the end of the ecliptic): a script sign, not identified
- P (left rim, upper)
- "Ecliptica." (diagonal, upper left): the ecliptic
- "Æquator." (diagonal, parallel to it): the equator
- C (centre, upper): the comet
- "Cometæ." (along the arc from C to R): of the comet
- R, V (right rim)
- G, I, D (between C and the horizon)
- E (star, right of D): with "Lucid. ♈", the Bright Star of Aries
- M, L (ends of the horizon); "Horizon." along it: the horizon
- Y, O, K (on the horizon)
- "Orbita" (lower left, rising from X): the orbit
- X (lower left rim)
- "Occidens." (lower field): west
- K (large, lower field): the figure's letter
- N (bottom rim)

• "Hor. 2 6′ 0″ m." (below the circle): at 2^h 6^m 0^s in the morning

Diagram. Figure L, the right of the two engraved figures, for the observation at 9^h 0^m 34^s in the evening. A circle with the zenith A at the top; the vertical A O runs down through the comet C, drawn as a small circle with a cross, and through H and D below it. The star B, the Bright Star of Aries, lies to the right of D, with E just above it; dotted lines run from C and H towards B and from B up towards V. The ecliptic runs on an arc from the left rim; the equator and the horizon run on two arcs from M to L; the orbit of the comet runs up from X at the bottom. "Autor ſculpſit" (the author engraved it) stands at the lower right of the plate.

• A (top of the circle): zenith
• S, V (upper rim, right of A)
• C (on the vertical): the comet
• H, D (below C on the vertical); W (beside D)
• E (just above B)
• B (star): with "Lucid. ♈", the Bright Star of Aries
• "Ecliptica." (arc from the left rim): the ecliptic
• [?] (outside the circle at the left rim): a script sign of the same form as in figure K, not identified
• M, L (ends of the horizon)
• "Æquator." (upper arc from M to L): the equator
• "Horizon." (lower arc from M to L): the horizon
• O, K (on the horizon)
• "Orbita Cometæ" (rising from X): the orbit of the comet
• "Meridies." (lower field): south
• L (large, lower field): the figure's letter
• X (bottom rim)
• "Hor. 9 0′ 34″. v." (below the circle): at 9^h 0^m 34^s in the evening
• "Autor ſculpſit" (lower right of the plate): the author engraved it

327

Even with the vertical parallax found in this way, however, we must not yet rest content with it as if it were the mean parallax; we must go on to investigate the prosthaphaereses of inclination, worked out from the earlier observation at $9^h\ 0^m\ 34^s$. These are indeed found by the same method shown above; but they are applied to the parallax of the orbit in an entirely different, indeed almost contrary, way than if the fixed star had lain either under the orbit itself or near it. For with those fixed stars removed at a right angle from the comet and its orbit, the proper motion is not taken into account; instead the matter is settled from the distances, according as the earlier or the later was greater or smaller. It is therefore extremely difficult, in any case where the fixed stars lie at a right angle towards the comet and its orbit, to grasp correctly whether the prosthaphaereses ought to be added or rather subtracted. We did indeed give certain rules for this purpose on p. 194, from which this very thing can be sought; but those can be extended only to the cases where the fixed star stands either under the comet's orbit itself or very near it, and where the apparent and true proper motion is considered. But since here the parallaxes are deduced entirely from the distances, and the fixed star stands at a right angle to the comet

[326] set unruled, in the page's own columns; the comet's azimuth calculation stands at the right in its first five rows. The marks are printed only over 76 51 at the right and over 23 38 41; the rest are supplied in the house form. "Sept." of the right-hand result is printed below "Occid.", at the line end of the next row. The angle K O is printed "8 34 0", where 76 51 0 less 68 17 5 gives 8° 33′ 55″; the complement of the star's altitude is printed "78 37 7", where 90° less 11° 22′ 59″ gives 78° 37′ 1″; both are kept as printed. The page names the angle here "E A C", where the text on the facing page names it "E A D"; kept as printed. The tags *A.* and *S.* and the direction tag *Occid. Sept.* are the page's own.

[327] set as the calculations above; the marks are printed over the first row and over 6 34; the result is printed without a degree figure, and none is supplied.

and its orbit, the prosthaphaereses, as I have just touched on, take on an almost contrary title, as the following axioms will make quite clear. They are divided into two classes. The first reveals the characters of the prosthaphaereses when the earlier observation, or distance, is parallel to the horizon, and the other, the later, is vertical; the second, when the earlier observation, or distance, is vertical, and the later parallel to the horizon. Just as these configurations of the comet with respect to the fixed star are most different from each other, so too the prosthaphaereses there obtain an entirely contrary effect.

[Margin: In hocce exemplo proſthaphæreſes inclinationis contrariâ planè ratione orbitæ parallaxi applicantur.] *In this example the prosthaphaereses of inclination are applied to the parallax of the orbit in an entirely contrary way.*

[Margin: Ardua res eſt, Fixis ad angulum rectum ratione Cometæ conſtitutis, affectiones proſthaphæreſium ritè dignoſcere.] *It is a hard matter, when the fixed stars are set at a right angle with respect to the comet, to discern the characters of the prosthaphaereses correctly.*

[Margin: Axiomata ab Autore traduntur pro titulis proſthaphæreſium, quæ in duas claſſes referuntur.] *Axioms are given by the author for the titles of the prosthaphaereses, which are arranged in two classes.*

Axioms [AXIOMATA.]

Of what character, that is, the prosthaphaereses are, of both the first and the second equation, when the earlier distance is parallel and the later vertical: that is, for those fixed stars standing at about a right angle with respect to the comet and its path. [Cujusnam nempè ſint affectionis, Proſthaphæreſes, tam primæ, quàm ſecundæ æquationis; exiſtente priore diſtantiâ parallelâ, poſteriore verò verticali : in iis nempè Fixis ſub normali circiter angulo, reſpectu Cometæ, ejusq́; viæ, exiſtentibus.]

[Margin: Prior claſſis.] *The first class.*

1. When the comet is above the fixed star and its perpendicular, in approach, the prosthaphaeresis is added to the parallax reduced to the vertical, so that the genuine equated vertical parallax results. But if the comet lies below the perpendicular so often mentioned above, B E, drawn in the figure on p. 176, or, in figure H above, the perpendicular B H, even though it seems to be above the fixed star, the prosthaphaeresis is Subtracted.
2. When the comet is below the fixed star, in approach, the prosthaphaeresis of inclination is subtracted.
3. When the comet is above the fixed star and its perpendicular, in recession, the prosthaphaeresis is subtracted; but if it lies below the perpendicular, even though it seems to be above the fixed star, the prosthaphaeresis is Added.
4. When the comet stands below the fixed star, in recession, the prosthaphaeresis is Added.

Axioms [AXIOMATA.]

When the earlier distance is given as vertical, and the later as parallel. [Datâ priore diſtantiâ verticali, & poſteriore parallelâ.]

[Margin: Poſterior claſſis] *The second class.*

5. When the comet is above the fixed star and its perpendicular, in approach, the prosthaphaeresis is Subtracted; but it is added if the comet is below the perpendicular, even though it lies above the fixed star.
6. When the comet is below the fixed star, in approach, the prosthaphaeresis of inclination is Added.
7. When the comet is above the fixed star and the perpendicular, in recession, the prosthaphaeresis is Added; but it is Subtracted if the comet is below the perpendicular, even though it stands above the fixed star.
8. When the comet lies below the fixed star, in recession, the prosthaphaeresis of inclination is Subtracted.

Although these axioms may seem extremely brief, they are nevertheless in truth very well founded, even though they are hardly easy for everyone to grasp at first sight, because they appear almost to conflict with the earlier ones. But whoever weighs this matter more exactly, with the aid of a globe and a well-constructed diagram, and also of the preceding axioms on distances given on p. 226, will readily admit that everything is entirely so. For example: in figure I above, and in the earlier observation, with the comet above the fixed star and in approach to it towards F, the earlier distance was given as greater than the later, according to the first axiom above, p. 226. But since the earlier, greater distance is somewhat diminished by reason of the parallax depressing the comet towards H, the difference of these distances (or the parallax), of which, that is, the greater has become a little diminished, becomes smaller by as much as that prosthaphaeresis of inclination C D requires; and therefore that prosthaphaeresis must necessarily be Added, just as our first axiom of the prosthaphaeresis also requires. You will be able to examine all the remaining cases in the same way, provided you first recognise correctly whether the comet lies in approach or rather in recession, and whether above or rather below the fixed star. You will find, however, that it is a matter of still deeper inquiry to judge correctly of what character the prosthaphaereses are, especially if the fixed star stands, in each distance, at an exactly right angle.

[Margin: Hæc axiomata ſolido nituntur fundamento,ut ut ſuperioribus quaſi adverſari videantur.] *These axioms rest on a solid foundation, even though they seem, as it were, to oppose the earlier ones.*

Now let us come to the calculation of the prosthaphaeresis itself, seeking first the altitude of the Bright Star of Aries for the earlier observation, with the aid of the preceding diagram L, in which the comet, in turn, is higher than the fixed star and, as is clear from figure I, lies in approach to it, or to the perpendicular E F. Therefore, according to the first axiom of the first class, just given, the prosthaphaeresis of both the first and the second equation is Additive, for the reason shown a little earlier.

[Margin: Sequitur Calculus.] *The calculation follows.*

	Parallax reduced to the vertical						6′ 34″	

334

Therefore the genuine vertical parallax, equated a second time, is 11′ 10″, namely for December 27 at 2^h 6^m 0^s in the morning, when the comet was at an altitude of 31° 12′ 13″.

But you may ask why this parallax does not belong to the altitude 67° 26′ 0″, that is, to the earlier observation, as happened in the earlier observations, especially in the preceding one, made from the same observations. I shall say: because there the earlier distance was always vertical and the later parallel to the horizon, whereas in this calculation the earlier distance was parallel to the horizon and the later almost vertical; and hence the parallax too belongs to

[334] set unruled, in the page's own columns, the step figures 1. to 4. standing at the head of their first rows; the marks are printed over 21 34 45 of step 1, over 62 31 0 and 14 31 0, and in 4 36; the rest are supplied in the house form; no figure is supplied. The signs + and the tags *A.*, *S.* and *Subt. Cosf.* are the page's own.

the later, vertical observation, namely to the altitude 31° 12′ 13″ — something I would like you to note well.

[Margin: Cui altitudini parallaxis modò inventa competat.] *To which altitude the parallax just found belongs.*

However, for the sake of greater certainty, let us seek this same parallax again, for the same altitude and from the same observations, but from different distances, namely those of the comet and Capella, which held an entirely different position with respect to the comet. Capella, it is true, likewise lay at about a right angle to the comet and its orbit, and in the first observation the distance was parallel to the horizon, while the other distance, in the second observation, was vertical. But in this second, vertical observation, at 2^{h} 6″ 0″ [recte: 2^{h} 6^{m} 0^{s}] in the morning, the Bright Star of Aries stood below the comet and Capella above it: a most different and entirely contrary configuration. So the parallax has also vitiated the distances in an entirely contrary way. Moreover, in the earlier, vertical distance, the Bright Star of Aries was below the comet, with respect to it, while Capella in the same earlier observation lay above it. Hence, in turn, in this following example the prosthaphaeresis of inclination will be subtractive, according to axiom 2, just as in the preceding example, with the Bright Star of Aries, it had been Additive, according to axiom 1.

[Margin: Ex diverſis nunc diſtantiis, parallaxis ad eandem altitudinem quæratur.] *Let the parallax for the same altitude now be sought from different distances.*

So much so that these cases are entirely conflicting and contrary to each other; and therefore both the method of our calculation and the parallax itself will become clear all the more certainly, namely whether it agrees with the earlier one or rather exceeds it. For if our calculation is liable to even the smallest error, that defect must show itself here; but if not, you can be all the more secure about these parallaxes of ours, both those already computed and those still to be computed.

Investigation of Parallax IX, from the Distances of the Comet and Capella, Computed, for December 27, Morning [Inveſtigatio Parallaxeos IX. Ex diſtantiis Cometæ & Capellæ ſupputatis, ad diem 27 Decemb. matut.]

For the earlier distance, E I.

1	Observation at 9^{h} 0^{m} 34^{s} in the evening	Altitude of the comet	67° 26′ 0″	*Orient.*

337

Since, then, it is still unknown whether Capella stood exactly at a right angle to the comet and its orbit or not, and likewise whether its proper motion between the two observations was slow or rather fast, we must first examine the distance of Capella from the orbit, and also the angle F I E, as being smaller than the other angle, F L E, in the following Figure M, so that the earlier distance E I may likewise be bounded with respect to E L and the proper motion entirely eliminated. But, you will say, why should E I be corrected here, as the smaller distance found, and not the larger, E L, as was taught above on p. 225? I admit, indeed, that I said the larger distance must always be corrected; but I remember that I also added: larger in itself. For although E L came out larger from the calculation, it was in fact smaller, and was somewhat larger only by reason of the parallax. For the comet was both in recession and, in the later observation, stood with the fixed star under the same verti- cal; there, since it was placed below the fixed star, it was depressed toward the horizon by the parallax, and consequently that distance E L was made a little smaller, as is clearly evident from diagram N. Therefore the earlier distance E I, as larger in itself, must now be limited in the usual way, according to that axiom on p. 225.

For the distance of Capella from the orbit, the angle F I E, and the limitation of the distance E I.

338

[Margin: Parallaxis Orbitæ.] *Parallax of the orbit.*

Although the later distance E L is here larger than the earlier one, I E, and the comet is approaching the fixed star, there is nevertheless parallax in these observations, according to our axiom 3, p. 227. Therefore the calculation must be continued, and this parallax must be brought back to the vertical by exactly the method used in the preceding calculation, except that the perpendicular D E in diagram N is computed from the complement of the altitude of the

338 set unruled, in the page's own columns, the part figures 1 to 3 standing at the head of their first rows. 				Parall. reduced to the vertical was			10′ 59″	

346

Therefore the genuine vertical parallax, equated a second time, is 7′ 51″, for the altitude of the comet 31° 12′ 13″, observed at 2^h 6^m 0^s in the morning on December 27.

This parallax is smaller by nearly three minutes than the earlier one, found in the preceding calculation from the distances of the comet and the Bright Star of Aries, even though it was derived from the same observations. Yet this is to be imputed neither to a faltering calculation nor to the calculator's carelessness. Rather, first, in the parallel observation the comet stood below the fixed star and in approach toward it, where the parallax is in a certain manner carried the opposite way; second, this very distance was too near the vertical point, and the angle B A C, namely 72° 45′ 10″, was too obtuse; third, beyond all doubt some small error still lies hidden in the longitude and latitude either of the Bright Star of Aries or of Capella, as is clearly evident from our more

346 set unruled, in the page's own columns, the step figures 1 to 4 standing at the head of their first rows. The marks are printed over 23 16 0 of step 1, over 68 6, after 180, and over 3 8 only; the rest are supplied in the house form; no figure is supplied, and step 4 prints its leading 0 as set. The signs + and the tags *A.*, *S.*, *S. Cosf.* and *Subtrah.* are the page's own.

recent observations. Hence this parallax could not be extracted as accurately as from the earlier, preceding computation, in which everything stands duly and consistently. Meanwhile, however, you see that the parallax comes out not larger, but a little smaller still, for the same altitude. So one is certainly moved to wonder that, from so very different a situation of the comet with respect to the fixed star and the distances, no more perceptible difference has nonetheless emerged.

[Margin: Cur hæc inventa parallaxis priori minor ſit ?] *Why is the parallax found here smaller than the earlier one?*

We have therefore shown sufficiently how great the parallax was on the 27th at $2^h\ 6^m$ [?] in the morning. Let us now also see how great it was at the evening hour of the same day, and indeed from quite different observations and distances. I do not doubt, my lover of the stars, that once you are fired with zeal for the truth you will hasten to these calculations with no less eagerness than the most ardent spirit with which I did not refuse to undertake and work out all of them, although with immense and most tedious labour, for your benefit and that of others.

[Margin: Licet faſtidioſiſſimus fuerit labor, cupidiſſimo tamen animo Autor calculos hos parallaxium iniit.] *Though the labour was most tedious, the author undertook these calculations of the parallaxes with the most eager mind.*

First, then, we shall set up the calculation from two distances of the comet and Aldebaran taken with the sextant, although one distance, parallel to the horizon, was observed in the morning at $2^h\ 6^m\ 0^s$ in the west, whereas the vertical distance was observed in the evening at $5^h\ 38^m\ 10^s$ in the east — and indeed in the manner we have indicated, about fixed stars near the orbit.

Investigation of Parallax X, from the Distances of the Comet and Palilicium Taken with the Sextant, for December 27 [Inveſtigatio Parallaxeos X. Ex diſtantiis Cometæ & Palilicii Sext. captis. Ad diem 27 Decemb.]

1	Observ. at $2^h\ 6^m\ 0^s$ in the morning	Distance of the comet	22° 5′ 30″	IE
2	Observ. at $5^h\ 38^m\ 10^s$ in the evening	Distance of the comet	24° 16′ 30″	LE
	Differ. of the hours $15^h\ 32^m\ 10^s$	Difference of the dist.	2° 11′ 0″	or the fictitious or mean apparent motion.

347

Now let this mean apparent motion be corrected, on account of the star's excessive distance from the orbit, so that the apparent motion reduced to the

[347]set unruled, in the page's own columns, the observation figures 1 and 2 at the head of their lines. The time marks are printed only over the first time, with no hour mark, and the angle marks only over the first distance; the rest are supplied in the house form; no figure is supplied.

orbit may result, by equating both distances of the comet, I E and E L, in Figure F on p. 218. This is done without difficulty, since the distance of Palilicium from the orbit is already known from Investigation VI.

Antil. of the earlier dist.	22° 5′ 30″	7625	IE.	
Antil. of the dist. of Palil. from the orb.	4° 38′ 0″	327 *S.*	EF.	
Antil. of the distance from the orbit, reduct.		7298		21° 37′ 27″
Antil. of the later dist. L E	24° 16′ 30″	9257		
Antil. of the distance from the orbit	4° 38′ 0″	327 *S.*		
Antil. of the dist. reduced to the orbit		8930		23° 51′ 20″ *S.*
Apparent motion reduced to the orbit				2° 13′ 53″
True motion from the table, corresponding to $15^h\ 32^m\ 10^s$				2° 20′ 5″

348

Since, therefore, this motion is greater than the apparent one, according to axiom 5 on p. 180, the parallax of the orbit hence comes out as 6′ 12″.

[Margin: Parallaxis orbitæ.] *Parallax of the orbit.*

Let this be reduced again to the vertical, for the hour, namely $5^h\ 38^m\ 10^s$ in the evening, with the comet and Palilicium almost standing under one and the same vertical circle — almost, I say, standing under one and the same vertical circle. Hence the angle of the orbit and the vertical must first be investigated. That angle, however, will hardly be found without labour, since the altitude of the comet is not yet known to us.

For the altitude of the comet at $5^h\ 38^m\ 10^s$ in the evening, and the azimuth.

[351] set as above, following the angle sought without a caption. The marks are printed over 6 12 and 6 18 only; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 6 12 or 6 18. The tag *S.* is the page's own.

To derive the prosthaphaeresis of inclination — in this place subtractive, according to axiom 5 for stars situated near the orbit — we need the altitude of the comet and of Palilicium at $2^h\ 6^m\ 0^s$ in the morning. The former is already known from calculation VIII; the latter, that of Palilicium, must still be computed.

Prosth. of the inclination of the first equat.		1′ 1″	Mesolog.	813034		

[354] set as above. The marks are printed only over the first row and over 74 49 34 in the fifth; the rest are supplied in the house form; no figure is supplied. The signs + and — and the tag *S.Cosf.* are the page's own; the tags *A.* and *S.* likewise.

[355] set as above. The marks are printed after 6 18 in the first row and over 1 1; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 6 18, 1 1 or 5 17. The tag *Subt.* is the page's own.

Angle of inclin. W C D, just found		5° 20′ 0″	Antilog.	434 *S.*	
Prosth. of the inclinat. of the second equat.	C D		Mesolog.	812600	1′ 1″ *Subt.*
Parallax reduced to the vertical was					6′ 18″
Therefore the true vertical parall., equated a second time					5′ 17″

For the altitude of the comet of 52° 17′ 7″, observed at 5^{h} 38^{m} 10^{s} in the evening on December 27.[356]

[Margin: Proſthaphæreſis verticalis ſecundò coæquata, planè cum primò coæquatâ coincidit.] *The vertical prosthaphaeresis, equated a second time, coincides entirely with the one equated first.*

And so you see that the prosthaphaeresis of the second equation is entirely the same as the earlier one of the first equation, so that nothing at all is taken from it on that account.

Moreover, for the following parallactic calculation, let us again use observations entirely different from the earlier ones — and indeed altitudes and azimuths. In the earlier observation, namely in the eastern quarter, the comet and Palilicium stood under almost the same vertical; in the later one, however, each stood at almost an equal distance from the horizon. Let the distances of the comet and Palilicium therefore be sought first, and then also the remaining quantities that are needed, according to our method and the three earlier figures F, P and Q.

Investigation of Parallax XI, from the Distances of the Comet and Palilicium Computed, for December 27 [Inveſtigatio Parall. XI. Ex Diſtantiis Cometæ & Palilicii ſupputatis ad diem 27 Decembr.]

1.	Observ. at	5^{h} 50^{m} 9^{s}	altit. of the comet	55° 6′ 0″	Azimuth, east	72° 19′	under the same vertic. circ.
2.	Observ. at	11^{h} 44^{m} 31^{s}	altit. of the comet	51° 52′ 40″	Azimuth, west	79° 36′.	

357

For the altitude of the comet of 55° 6′ 0″, observed at 5^{h} 50^{m} 9^{s} in the evening on December 27.[368]

Since this parallax seems almost too slight, we shall compute it once more from the same observations, but from entirely different distances, namely those

[367] set as above. The marks are printed only over 25 19 20 in the first row, over 89 11 0 in the third and over 6 39 0 in the sixth; the rest are supplied in the house form; no figure is supplied. The signs + and the tags *S.*, *A.* and *Subt. Cosf.* are the page's own.

[368] set unruled, in the page's own columns, continuing the calculation of the previous page. The marks are printed only after 0 32 and 0 33; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 0 32, 0 33, 1 57 or 2 30. The signs + and the tags *A.* and *S.* are the page's own. The words "For the altitude" close the last row on the page and run on into the line below.

of the comet and of the fixed star in the bend at the hips of Cassiopeia. Relative to that star, indeed, the comet had a position far different from its position relative to Aldebaran: with respect to Palilicium it was receding, but with respect to this fixed star it was approaching. Then, in the earlier observation, this star at the hips of Cassiopeia stood very close both to the orbit and to the vertical, and in the later observation on a parallel [?] below the perpendicular B H. Since this is an entirely different configuration of the phenomenon, it will become known all the more truly whether some fault lies hidden in the calculation or rather in the observations themselves. The procedure of the whole operation, however, is entirely the same, except that diagrams R and S are to be substituted in place of F and Q.

[Margin: Genuina parallaxis verticalis ad diem 27 hor. veſp.] *The genuine vertical parallax for the 27th, at the evening hour.*

Investigation of Parallax XII, from the Distances of the Comet and the Fixed Star at the Hips of Cassiopeia, to Be Computed, for December 27 [Inveſtigatio Parallaxeos XII. Ex diſtantiis Cometæ & Fixæ ad Coxas Caſſiopeæ ſupputandis, ad diem 27 Decemb.]

372

[Margin: Diſtantia fixæ ab orbita.] *The distance of the fixed star from the orbit.*

Diagram. One engraved plate in a ruled frame, holding two figures side by side. At the left, figure R: a tall, narrow figure standing on an arc of the ecliptic. From A at the apex, arcs descend to H, C, B and G on the ecliptic; a line marked as the orbit of the comet crosses the figure obliquely; the fixed star at the hips of Cassiopeia stands as a star at E, with D and K to its left, joined to E by dotted lines; small circles mark L and I on the left-hand arcs; a large italic R stands in the middle. At the right, figure S: a circle with A at the top and the horizon drawn as an arc from M at the left to L at the right, O standing on it at the foot of the vertical from A. The comet's orbit runs from M across to L; on it lie the comet C, drawn as a small circle with H above it and D and W below, and the star B, marked as the star at the hips of Cassiopeia. S and V stand on the rim at the upper right, joined to B by a solid and a dotted line; E

371 set as above. The marks are printed over 23 23 24 and 17 5 57, after 41 13 30, and above 40 20 45 and 33 42 57; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 46 3, 47 15 or 1 12. The sign ♉ and the tags *A.* and *S.* are the page's own.

372 set unruled, in the page's own columns. The marks are printed only over 9 11 42 and after 51 32 40 and 5 29; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 7 0 or 5 29. The sign ♉ and the tags *A.* and *S.* are the page's own. On the page the rows from the first "Hyp." to the second stand to the right, under the logarithm columns.

stands above B, joined by a dotted line; P stands on the rim at the left and a script capital E on the rim at the upper left; K stands below the horizon at the right; the equator and the ecliptic run down to the rim at the lower right, the ecliptic to N; "the west" and a large italic S stand in the lower half. Below the circle is the hour legend, and at the lower right the engraver's signature.

- Figure R: A (apex); "Orbita Cometæ" (along the oblique line): the orbit of the comet; "Ad cox. Coſ." (beside the star E): at the hips of Cassiopeia; D, K (left of E); E (the star); L, I (small circles on the left-hand arcs); R (figure letter, middle); "Ecliptica" (the arc at the foot): the ecliptic; H, C, B, G (on the ecliptic).
- Figure S: A (top); E, in a script capital (rim, upper left); S, V (rim, upper right); P (rim, left); H, C, D, W (at the comet, left of centre); E (above B); B (the star); "Ad cox. Caſs." (beside B): at the hips of Cassiopeia; "Orbita" … "Cometæ." (along the arc from M to L): the orbit of the comet; M, L (ends of the horizon); "Horizon." (along the arc M–L): the horizon; O (on the horizon); K (below the horizon, right); the label on the upper of the two arcs at the lower right, its first letter an engraved script capital not separated between A and the Æ ligature, then "quator.": the equator; "Ecliptica." (the lower arc): the ecliptic; N (rim, lower right); "Occidens.": the west; S (figure letter, lower half); "Hor. 11 44′ 31″ v." (below the circle): at $11^h\ 44^m\ 31^s$ in the evening; "Autor ſculpſ." (lower right): the author engraved it.[373]

Since this distance is only a few minutes, no reduction to the orbit is therefore needed, but only a reduction to the vertical. You will carry this out very easily, because the angle of the vertical and the orbit is already known from the preceding inquiry, namely for the hour $5^h\ 50^m\ 9^s$; although, indeed, this vertical reduction too will contribute very little to the mean parallax, so that it could rightly be omitted.

[Margin: Nullâ reductione ad orbitam hîc opus eſt.] *No reduction to the orbit is needed here.*

For the reduction to the vertical.

Mesol. of the side C G, or of the fictitious parall., at the same time that of the orbit		1′ 12″	796025

Genuine vertical parall., equated a second time			2′ 7″	for the altit. of the com. 55° 6′, at $5^h\ 50^m\ 9^s$.		

377

It differs by only a very few seconds from the parallax derived in the preceding investigation, namely from the distances of the comet and Palilicium; and it is still, roughly, somewhat smaller than that one. So there is no fault whatever in the calculation; but if there is any, it lies hidden rather in the observations, above all in that later one made at $5^h\ 50^m\ 9^s$. Let us therefore continue with a further reckoning of this parallax, and in place of the earlier observation we shall use another, made at $5^h\ 40^m\ 48^s$, in which the altitude, together with the azimuth of the comet, was observed with the greatest care. From this observation, then, and from that later one at $11^h\ 44^m\ 31^s$, let us investigate the parallax through the distances of the comet and the Bright Star of Aries. For this fixed star stood, relative to the comet, in a very convenient configuration: at that time the comet was approaching the fixed star, while the star, for its part, lay at an almost right angle to the comet and its orbit. Moreover, in the earlier observation the distance ran parallel to the horizon, and in the later one, in turn, it was vertical. From this fitting position, for the altitude of the comet of 51° 52′ 40″, namely at $11^h\ 44^m\ 31^s$, with the fixed star and the comet under the sa-

[Margin: In calculo nihil omninò aberratum; cùm æqualis propemodùm parallaxis illâ præcedente calculo erutâ, inventa fuerit.] *No error at all was made*

377set as above. The marks are printed over 33 42 57 in the first row and after 78 56 (third row), 21 50, 53 6, 0 49, 0 54 and 55 6, and over the minutes and seconds of the time; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 0 49, 0 54, 1 13 or 2 7. The tags *A.*, *S.*, *S. Cosf.* and *Add.* and the signs + are the page's own.

in the calculation, since a parallax almost equal to the one derived by the preceding calculation has been found.

[Margin: Vlteriori ratiocinio eadem parallaxis inveſtigatur.] *The same parallax is investigated by a further reckoning.*

me vertical, nothing but a most accurate parallax is to be expected, one to be preferred to the two preceding ones found for about the same time. Since, however, the Bright Star of Aries held a position perpendicular to the comet and its orbit, we must now set up the operation differently from the way it was done in the preceding calculation, as we have already pointed out several times.

Investigation of Parallax XIII, from the Distances of the Comet and the Bright Star of Aries, to Be Computed, for December 27 [Inveſtigatio Parallaxeos XIII. Ex diſtantiis Cometæ & Lucidæ Arietis ſupputandis, ad diem 27 Decembr.]

For the earlier distance E I.

Parallax of the orbit			5′ 34″				

382

[Margin: Parallaxis Orbitæ.] *The parallax of the orbit.*

This is to be brought back to the vertical, as in- vestigation VIII was shown. For the calculation must be continued, since the earlier distance is greater than the later, and some parallax lies hidden here, according to axiom 2. This is done by seeking the angle E C D in Diagram V from the azimuths of the comet and of the Bright Star of Aries: the azimuth of the comet is indeed already given by the observation, while that of the star must first be determined; and so one must proceed further, step by step.

[Margin: Parallaxin ſubeſſe deprehenditur.] *A parallax is found to be present.*

Diagram. Figure T, at the left of the row of three figures: a spherical triangle with its apex A at the top, the comet's orbit drawn up its left side and the ecliptic along its foot, with dotted construction lines running from two

[381] set as above. The marks are printed after 21 24 33 and 82 12 15; the rest are supplied in the house form; no figure is supplied. The tag *S.* is the page's own. No figure T is printed on this page.

[382] set as above. The marks are printed after 48 30 and 48 10, and as column heads over 5 40 and over 21 19 49; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 48 30, 48 10, 5 40 or 5 34. The tags *A.* and *S.* and the sign of Aries ♈ are the page's own. The parallax of the orbit is printed 5 34, where 21° 19′ 49″ less 21° 12′ 15″ gives 7′ 34″; the printed figure is kept.

small circles on the left side to the star E. The figure is cut at the left by the gutter.

- A (apex, top): A
- running up the left side: *Orbita Cometa.* — orbit of the comet
- K (right side, upper): K
- D (right side, below K): D
- F (left edge, at the gutter): F
- L (left edge, beside the upper small circle): L
- M (below the lower small circle): M
- beside the star E: *Lucid.* ♈ — the Bright Star of Aries
- E (the star, right): E
- T (large figure letter, lower left): T
- along the foot: *Ecliptica.* — the ecliptic
- lower left corner, at the gutter: [?] (the right half of a sort, perhaps B)
- C (foot, left): C
- G (foot, right): G

No letter is seen beside the lower small circle on the left side, although the calculations cite I there; it may stand in the binding shadow.

Diagram. Figure V, in the middle: a circle with the horizon drawn across it, the equator and the ecliptic, the comet's orbit, and the vertical circles through the comet C and the star E. The caption under the circle gives the hour.

- rim, top: A
- rim, upper left: V
- rim, left of V: an engraved sign, an open C-shaped stroke with a small loop [?]
- rim, upper right: S
- rim, left: P
- C (the comet, on the orbit): C
- across the upper part: *Orbita Cometæ.* — orbit of the comet
- rim, right: R
- I (below C, left): I
- G (below C, right): G
- D (left of E): D

	Parall. reduced to the vertical	5′ 41″			
Therefore the genuine vertical parallax, equated a second time at $11^h\ 44^m\ 31^s$ in the evening, observed on December 27.		5′ 26″	For the altitude of the comet	51° 52′ 40″,	

391

Since this is about two minutes greater than in the two preceding computations, we shall therefore compute the same parallax once more from the same observations, for the same altitude, and indeed from quite different distances, namely of the comet and Capella. In the west, namely in the vertical observation, Capella stood above the comet, as the Bright Star of Aries in the earlier calculation stood below it; moreover, Capella was in recession, the Bright Star of Aries in approach, not to mention that in the parallel observation Capella was placed above the perpendicular B H, the Bright Star of Aries below it. If, from this very different position of the fixed stars relative to the comet, almost the same parallax comes out of every calculation, you will judge quite rightly that it has been computed entirely and correctly, and that it is genuine.

[Margin: Pro majori rei certitudine denuò eadem ſupputatur parallaxis.] *For greater certainty in the matter, the same parallax is computed anew.*

[Margin: Si omninò eadem ex omni calculo provenit parallaxis, de obſervationibus & ſupputatione ſecuri prorsùs eſſe poſſumus.] *If entirely the same parallax results from every calculation, we can be wholly confident of the observations and of the computation.*

Investigation of Parallax XIV, from the Distances of the Comet and Capella, Computed, for December 27 [Inveſtigatio Parallaxeos XIV. Ex diſtantiis Cometæ & Capellæ ſupputatis, ad diem 27 Decemb.]

For the earlier distance. E L.

1	Observ. at $5^h\ 40^m\ 48^s$	Altit. of the comet	53° 33′ 30″	Azim. east	75° 14′	Parall.
2	Observ at $11^h\ 44^m\ 31^s$	Altit. of the comet	51° 52′ 40″	Azim. west	79° 36′	Vertical.

391 set unruled, in the page's own columns, continuing the calculation of the previous page. The marks are printed after 21 24 33 (first row), 77 53 0, 51 52 40 and the minutes and seconds of the hour; as column heads over 87 45 and over 0 15; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 0 14, 0 15, 5 41 or 5 26. The 0 before 53 8 is printed. The tags *A.*, *S.* and *S. Coſ.*, the sign +, and the abbreviation *Subt.* are the page's own.

Diagram. An engraved figure across the page in a plate-mark frame, of three diagrams side by side. At the left, X: a tall spherical triangle with its apex at A, the arc marked "Orbita Cometæ." *Orbit of the comet* running down the right side, the star Capella at E on the left, and the ecliptic along the base. In the middle, Y: a circle cut by the horizon, the comet's orbit, the equator and the ecliptic, with Capella at E and C at a small circle on the comet's orbit, marked "Occidens." and dated to $11^h\ 44^m\ 31^s$ in the evening. At the right, Z: a circle with the same lines, Capella at B and C at a small circle, marked "Oriens." and dated to $5^h\ 40^m\ 48^s$ in the evening. The engraver's signature stands at the lower right. Labels as printed, from the top down:

- X: A (apex); "Orbita Cometæ." *Orbit of the comet* (set vertically along the arc at the right); M; I (at a small circle); L (at a small circle); "Capella" and E (at a star, left); F; X (centre); "Ecliptica." *Ecliptic* (along the base arc); G, H, C, B (along the base).
- Y: F, A (top); [?] (an engraved sort at the upper left, outside the circle, not resolved to a letter); "Cap. E" (at a star); D; I; S (upper right); P, T (left); C (at a small circle on the orbit); "Orbita Cometæ." *Orbit of the comet*; R (right end of the orbit); M (left end of the horizon); "Horizon." *Horizon*; L (right end of the horizon); K, O (below the horizon); "Occidens." *West*; Y; "Æquator." *Equator*; "Ecliptica." *Ecliptic*; N (end of the ecliptic, lower right); "Hor. II 44′ 31″ v." *At $11^h\ 44^m\ 31^s$ in the evening* (under the circle).
- Z: R, A (top); V, S (upper left); E; "Capella." and B (at a star); C (at a small circle); H; D; W; M (left end of the horizon); "Horizon." *Horizon*; L (right end of the horizon); T, O (below the horizon); K; "Ecliptica." *Ecliptic*; "Æquator." *Equator*; "Oriens." *East*; Z; "Orbita Cometæ." *Orbit*

400 set unruled, in the page's own columns, continuing the calculation of the previous page. The marks are printed after 22 45 55 and 16 48 39; the rest are supplied in the house form; no figure is supplied. The tags *A.* and *S.* are the page's own. The page prints the sum as 30° 22′ 32″, where 22° 45′ 55″ and the difference of altitudes on the previous page (7° 36′ 38″) give 30° 22′ 33″; and it prints 284119 for the difference of the two aggregates, where 336544 less 88425 gives 248119, whose half is the 124059 printed below it. Both printed figures are kept.

of the comet (set vertically); X (end of the orbit, lower right); "Hor. 5 40′ 48″ v." *At 5^h 40^m 48^s in the evening* (under the circle); "Autor fculps." *The author engraved it* (lower right).[401]

404

It is therefore plainly established that all the computations made for the parallaxes of the 27th agree with one another extremely well; so that, since one

[403] set as above. The marks are printed after 22 45 55 and after 84 13; the rest are supplied in the house form; no figure is supplied. The tag *S.* is the page's own.

[404] set unruled, in the page's own columns, continuing the calculation of the previous page. The marks are printed after 22 45 55, 7 26, 71 53, 1 59 and 51 52 40, and over the minutes and seconds of the hour; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 1 56, 1 59, 5 47 or 3 49. The tags *A.*, *S.* and *S. Cosf.*, the sign +, and the abbreviation Subtr. are the page's own. The page prints 3′ 49″ for the parallax equated a second time, where 5′ 47″ less 1′ 59″ gives 3′ 48″; the printed figure is kept.

parallax exceeds the other by scarcely a single minute, and more rarely by a little more, we may rightly rest content with this day. Now, for computing the parallaxes for December 28, there first present themselves to us the distances of the comet and Capella taken with the sextant: the earlier, parallel to the horizon, at $5^h\ 35^m\ 6^s$ in the evening on the 27th; the later, vertical, observed at $1^h\ 44^m\ 10^s$ in the morning on the 28th. Yet it is for this later one that the parallax is to be derived.

[Margin: Cùm omnes ſupputationes ritè inter ſe conveniant, neutiquam parallaxis in dubium vocari poteſt.] *Since all the computations agree properly with one another, the parallax can in no way be called into doubt.*

Investigation of Parallax XV, from the Distances of the Comet and Capella Observed with the Sextant, for December 28 [Inveſtigatio parall. XV. Ex Diſtantiis Cometæ & Capellæ Sextante obſervatis, ad diem 28 Decembr.]

1	Obs. at $5^h\ 35^m\ 6^s$ on the 27th, in the evening	Distance of the comet and Capell.	22° 48′	Parall.
2	Obs. at $1^h\ 44^m\ 10^s$ on the 28th, in the morning	Distance of the comet and Capell.	22° 52′	Vertical.
	Differ. $8^h\ 9^m\ 4^s$	Different.	4′	

405

1. Let the angle F L E be sought from the preceding figure Y; for the distance of Capella from the orbit has already been determined.

Earlier distant.	22° 48′ 0″	Logar. 94800	
Dist. of Capell. from the orbit E F	22° 50′ 32″	Logar. 94619 *S.*	
Angle F L E		Logar. 181	86° 33′ 0″

406

For the reduction and limitation of the earlier dist. E I.

[405] the time marks are printed only over the minutes and seconds of the first time, and the angle marks only after the first distance; the rest are supplied in the house form; no figure is supplied. The words Parall. and Vertical. stand at the right ends of the two lines, as printed.

[406] set unruled, in the page's own columns. The marks are printed after 22 48 0 and 86 33 0; the rest are supplied in the house form; no figure is supplied. The tag *S.* is the page's own. The page gives the distance of Capella from the orbit as 22° 50′ 32″ with the logarithm 94619, where the computation for December 27 two pages earlier gives 22° 50′ 37″ with the same logarithm; both are kept as printed.

414

For a further inquiry into the parallax of this day, the 28th, we shall keep, in the following calculation, that earlier observed distance at 1^h 44^m 10^s, and add to it a new observation, made on the 29th at 4^h 10^m 50^s, likewise obtained with the sextant. We shall labour so that the parallax can equally be derived accurately from observations of this kind, made on different days. It should, however, be carefully noted that these observations are very different from all the others that have served us so far. For the said distances were both observed in one and the same western quadrant, whereas until now we have always

414 set as above. The marks are printed after the first 22 48 0, after 3 13 and 34 36 17, and over the minutes and seconds of the hour; as column heads over 76 2, and over 69 26 as a degree circle and a double stroke, which the 69° 26″ keeps; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 3 12, 3 13, 8 29 or 5 16. The subtraction of 69 26 from 76 2, giving the 6 36 printed, takes the 26 as minutes. The tags *A.*, *S.* and *S. Cos.*, the sign + and the point-letters are the page's own; 8 24 is set without marks and is taken as degrees and minutes, the column's form.

chosen for our parallactic computation one taken in the eastern region and the other in the western, or the reverse. In addition, both distances also lay on the same vertical circle, and neither of them was parallel to the horizon. This is certainly worth noting. For in the earlier observation the comet stood 34° above the horizon, but in the later only 16°, and so it was subject to refractions. It is therefore of the greatest importance that the later distance be freed entirely of all refraction, by means of the small table that follows.

[Margin: Ex duabus diſtantiis, in uno eodemq́; quadrante obſervatis ſubducere parallaxin.] *To compute the parallax from two distances observed in one and the same quadrant.*

[Margin: Refractio hic adhibenda.] *Refraction is to be applied here.*

And since every refraction raises any phenomenon whatever, it is necessarily always subtracted from the altitude. Here, however, since Capella stood at a right angle with respect to the comet and its orbit, and also above the comet in that same later observation, the refraction diminished that distance by raising the comet toward Capella; so here the refraction must be added to the distance. But if the comet had stood above the fixed star, the refraction would necessarily have had to be subtracted, and I urge you to keep this in mind again and again.

[Margin: Omnis refractio phænomenon attollit.] *Every refraction raises the phenomenon.*

On the refractions to be applied to comets, I would have you know this: that one refraction belongs to the Sun, the Moon and the planets, and another in turn to the fixed stars (as there is no student of the stars who has not established it). Accordingly I consider it most fitting, in my judgement, that comets too should have refractions of their own applied to them. For the bodies of comets are, for the most part, smaller in appearance than the bodies of the luminaries, and yet again they are found to be larger than even the fixed stars of the first magnitude; moreover, they move more often in the region of the planets, that is, above the Moon and below the fixed stars. For this reason I thought I would not be acting wrongly if I took a middle course, and set for the comets refractions a little smaller than the Moon's and, again, a little larger than those of the fixed stars: such as I now present in the small table attached.

[Margin: Quales refractiones adhibendæ ſint Cometis.] *What refractions are to be applied to comets.*

Investigation of Parallax XVI, from the Distances of the Comet and Capella Taken with the Sextant, for December 28 [Inveſtigatio Parallaxeos XVI. Ex diſtantiis Cometæ & Capellæ Sext. captis, ad diem 28 Decembr.]

1.	Observ. at $1^h\ 44^m\ 10^s$ *m.*	on December 28	Distance of the comet and Capell.	22° 52′ 0″ in the west.
2,	Observ. at $4^h\ 10^m\ 50^s$ *m.*	on December 29	Distance of the comet and Capell.	22° 46′ 0″
	Differ. $26^h\ 26^m\ 40^s$		Refraction at about 14° or 15° of alt.	6′ 30″
			Later distance corrected	22° 52′ 30″
			Difference of the earlier and the later corr. distances	30″

416

[Margin: Differentia diſtantiarum nonnunquam genuinam parallaxin illicò detegit.] *The difference of the distances sometimes reveals the genuine parallax at once.*

Now if the comet had exercised no proper motion at all, and both observations had been vertical, the difference of the distances between about 34

415a ruled table in a frame, its caption inside the frame (Tabella Refract. Comet.). Two pairs of columns, divided by a double rule; each altitude column is headed Altit. Comet. and each refraction column Mi.Se., minutes and seconds. The cells print the figures only; the altitudes are kept as printed, and the minute and second marks are supplied in the house form under the printed head; no figure is supplied. Rules divide the rows in groups of three. No labels stand at the foot of the table.

416set unruled, in the page's own columns, the observation figures 1 and 2 at the head of their lines, the second followed by a comma, as printed. The time marks are printed only over the first time, with no hour mark, and the angle marks only over the first distance; the rest are supplied in the house form; no figure is supplied. The 6 30 stands under the minutes and seconds of the distance above it, and the 30 under its seconds. The abbreviation *m.* after each time is never expanded on the page and is kept as printed.

and 16 degrees of the comet's altitude would be the genuine difference of the parallaxes. However, since $26^h\ 26^m\ 40^s$ elapsed between the two observations, and the comet possesses a proper motion, the later distance was corrupted; and so that motion must of necessity first be entirely eliminated from the distances. Next we shall also try to derive the parallax by reducing one distance to the vertical and the other to the parallel of the horizon. And finally, from the same observations, we shall endeavour to investigate the genuine difference of parallax by a method entirely unknown before now.

[Margin: Methodo hucusq; incognitâ parallaxeos differentiam invenire.] *To find the difference of parallax by a method unknown until now.*

Differ. of the dist., or fictitious parall.		2′ 6″			

417

[Margin: Parallaxis ficta.] *The fictitious parallax.*

This fictitious parallax must now be brought back to the vertical, since E I, the later distance, is greater than the earlier, E L, so that, according to axiom 5, a parallax really is present in the observations. This can easily be done, since the angle E C D, namely of the comet's vertical and of the distance of the comet and Capella at the given hour, $1^h\ 44^m\ 10^s$, is already known from the preceding calculation.

Diagram. An engraved figure in a plate frame, set at the left beside the opening paragraph and lettered AA: a circle crossed by great-circle arcs and straight lines, with dotted lines running from F to the star at B and from B

[417] set unruled, in the page's own columns. The marks are printed after 22 52 30 (first row), 87 3 30, 2 55 52, 9 6 and 22 54 6; the rest are supplied in the house form; no figure is supplied. The 2 56 6 stands in the column of the degree figures above it, and the 2 6 under the minutes and seconds of 22 54 6. The tags *A.* and *S.* and the point-letters are the page's own; the caption names E I, and the second-to-last row names E L, as printed.

and I towards V. The arcs are named in script as the ecliptic, the equator, the horizon and the orbit of the comet; the star at B is named as Capella; the word for the west stands inside the circle below the orbit. Under the circle the hour is engraved, and at the lower right the engraver's line. No letter G stands on the figure, although the calculation below names the side C G.

422

This parallax agrees very well with the one derived from the preceding calculation: the difference is scarcely one minute, even though it was derived from very different observations, and likewise by a different method. But the two would agree still better if the comet had not been subject to refractions in

[421] set unruled, in the page's own columns, continuing the calculation of the angles begun on the previous page. The marks are printed after 13 3 55, after the middle 12 31 56 and after the left 2 8, and as column heads over 73 18 9, over 88 8 15 and over 1 51; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 24 51, 2 8, 1 51 or 3 59. The tags *A.*, *S.* and *S. Cosf.*, the sign +, the long dash after 342593 and the point-letters are the page's own. The page prints the antilogarithm of A E as 124717, where 127158 less 2411 gives 124747; all three are kept as printed.

[422] set as above. The marks are printed after both 22 52 30, after 56 4, 19 42, 31 54, 2 2 and 34 36 17, and over the minutes and seconds of the hour; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 1 51, 2 2, 2 8 or 4 10. The tags *A.*, *S.* and *S. Cosf.*, the sign + and the point-letters are the page's own; the abbreviation *m.* after the time is kept as printed.

the later observation; above all, if we had applied to it Tycho's refraction of the Moon, 7′, the parallax would then have come out at 5½′. So there should now be no doubt at all about this parallax on the 28th.

[Margin: Hæc parallaxis haud malè cum priore convenit.] *This parallax agrees not badly with the earlier one.*

It remains for us now also to show, as we promised at the beginning, how the difference of the parallaxes ought to be computed from observations of this kind: namely, when in both observations the angle B C A, with the comet standing below the fixed star (or, with it above the fixed star, the angle B C D), does not exceed 30 or 40 degrees.

[Margin: Ex quibus obſervationibus differentia tantùm parallaxeos inveſtigari poſſit.] *From which observations only the difference of parallax can be investigated.*

Having found this angle B C A of the later observation, then, let its antilogarithm be subtracted from the mesol. of the side C G of the fictitious parall.; at once there results the mesol. of the parall. reduced to the vertical for the later observation. Take this away from the parallax reduced to the vertical for the earlier observation, and you will have the difference of the parallaxes itself. It is better, however, if the observations permit it, to compute the parallax for a definite altitude, as has also been done by us until now. But when you have observed both distances almost at the same time, or the one shortly after the other, and that in the same quadrant, where the angle B C A or B C D is very acute, so that impos- sible to investigate the parallax for a definite altitude; then, I say, one must proceed by the way shown here, by which the difference of the parallaxes may become evident. For example:

Mesol. of the side C G of the fict. parall.	2′ 6″	740064	
Antil. of the angle B C A	28° 2′ 44″	12493	
		S.	
Mesol. of the parall. reduced to the vertical, later observ.		727571	2′ 23″
The earlier parall. reduced to the vertical was			2′ 8″
Therefore the diff. of the parall. between 34 and 16 deg. of altit. of the com.			15″ is only; if you add it
to the parallax equated a second time,			4′ 10″ there results the genuine parallax
for the altit. of the other observation,			4′ 25″ namely 16 deg. 17 min.:

423

[Margin: Genuina Parallaxis.] *The genuine parallax.*

[423] set unruled, in the page's own columns; the last three rows are one sentence, its words running on after the figures to the end of each line, as printed. The marks are printed after 2 6 and 2 23 only; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 2 6, 2 23, 2 8, 15, 4 10 or 4 25. The tag *S.* and the point-letters are the page's own.

since this altitude is lower than the earlier one. Otherwise, if the later altitude is greater than the earlier, let it be subtracted from that same parallax.

This difference of the parallaxes ought, indeed, to have been a little greater, by about 15 seconds. But this arises only from an angle that is too large; had the angle been somewhat smaller, the difference of the altitudes would also have come out more correct. Meanwhile, however, anyone skilled in these matters will marvel with me that, by keeping to this method, we can still derive the vertical parallaxes themselves for each observation so exquisitely that only a very few seconds are lacking.

[Margin: Quòd etiam hâc viâ æq̃; accuratè parallaxis erui posſit, meritò admiramur.] *That the parallax can be derived just as accurately by this way too, we rightly admire.*

Now that we have investigated the parallax for the 28th, let us therefore go further and inquire into it likewise for December 29, although very few observations were made on that day from which this could conveniently be done. We shall nevertheless take pains that this task can be accomplished in the following calculation, by means of the observed distances of the comet and Capella. We shall keep the later observation, namely the preceding one, of the 29th at $4^h\ 10^m\ 50^s$ in the morning, with the fixed star and the comet standing under the same vertical; and we shall add to it another, a parallel distance observed on the 30th at $6^h\ 41^m\ 50^s$ in the evening, since it did not happen that two could be taken together on that same day, the 29th. Since, however, in the earlier observation, on the 29th, the comet was quite near the horizon, the distance must first be corrected for refraction, and then the difference of the distances must be limited by the true proper motion. For this limitation the distance of Capella from the orbit of the comet is required, to be computed again from Figure X. For since both the angle of the orbit and the ecliptic and the point of intersection are now beginning to vary noticeably from day to day, the distance of Capella found above can be of no further use to this calculation.

[Margin: Ex quibus obſervationibus parallaxes ad diem 29 Dec. ſupputari debeant.] *From which observations the parallaxes for December 29 are to be computed.*

Investigation of Parallax XVII, from the Distances of the Comet and Capella Observed on December 29 and 30 [Inveſtigatio Parallaxeos XVII. Ex diſtantiis Cometæ & Capellæ obſervatis, die 29 & 30 Decemb.]

	Therefore the genuine vertical parallax, equated a second time		5′ 26″	For the altitude of the comet	
16° 17′, observed on December 29 at 4^h 10^m 50^s *m.*; which was to be computed.					

[432]

However, since no other observations remain for the 29th, let us turn to the 30th. Let us therefore investigate the parallax, first from the distances of the comet and the Heel taken at 6^h 10^m 30^s in the evening on December 30, and at 3^h 37^m 26^s in the morning on December 31. Since these were not observed with instruments, it is neces-

[Margin: Calculus parallaxeos pro die 30 Decemb.] *Calculation of the parallax for December 30.*

[432] set as above. The marks are printed after 23 27 0 (set above the figures), after 2 5, after 16 17 and over the minutes and seconds of the hour, and as column heads over 76 26 34 and 56 24 17; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 1 58, 2 5, 3 21 or 5 26. The tags *A.*, *S.* and *S. Cofs.*, the sign + and the point-letters are the page's own; the abbreviation *m.* after the time is kept as printed.

sary first to derive them from the longitudes and latitudes. For the earlier observation, the longitudes and latitudes were determined from distances, and there refraction would necessarily have had to be taken into account, unless the comet had stood 66° high at that time. For the later observation, however, the longitudes and latitudes came out of altitudes and azimuths corrected for refraction, so that no further correction is needed here. I was glad to point this out at this place, partly so that you may see my care, and partly so that you may not be unaware of when, and in which distances, refractions are to be applied.

Investigation of Parallax XVIII, from the Distances of the Comet and the Heel, Computed, for December 30 [Inveſtigatio parall. XVIII. Ex Diſtantiis Cometæ & Calcanei ſupputatis, ad diem 30 Decembr.]

1 Obs. Dec. 30, at	6^h 10^m 30^s in the evening.	The comet and the Heel under the same vertical circle.			
2 Obs. Dec. 31, at	3^h 37^m 26^s in the morning.	The comet and the Heel almost equidistant from the horizon.

		Fictitious parallax, or parallax of the orbit	39″	

436

[Margin: Parallaxis Orbitæ.] *The parallax of the orbit.*

Although this fictitious parallax, or parallax of the orbit (namely the difference between the apparent and the true motion), is very slight, and is almost the vertical parallax itself, at an altitude of 67° on the 30th at $6^h\ 10^m\ 30^s$, so that it can differ only very little from the true and genuine parallax, nevertheless, as is our custom, since the matter is difficult, let us first reduce it to the vertical, and then investigate its prosthaphaeresis of both the first and the second equation, so that it may come out all the more accurately how great the parallax is altogether at the given altitude: whether, that is, it is still gradually decreasing or not.

Diagram. The left of three engraved figures set side by side across the measure. Three arcs are drawn down from A to an arc at the foot marked G, H, C, I; the orbit of the comet runs up to the right through L and I. Dotted

[435] set as above. The marks are printed after 56 17 12, after 12 21 0 and after 1 6 15; the rest are supplied in the house form; no figure is supplied. After 12 in the fifth line the page prints a minute mark where a degree mark would stand, and it is given as printed. The tags *A.* and *S.* and the point-letters are the page's own.

[436] set unruled, in the page's own columns, continuing the calculation above. The marks are printed after 12 9 9, after 12 6 11 and after the minutes and seconds of the hour; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 37 9 or 37 48, nor any minute figure before 39. The tag *S.* and the point-letters are the page's own. The page prints the antilogarithm of I F as 2485.882, where 2504.252 less 18.570 gives 2485.682; all are kept as printed.

lines join D and K on the left arc to I and L. The star E (marked by a star), labelled "Calc." above and "Algol." below, is joined by straight lines to I and L, by dotted lines to D, K and F, and by a dotted arc down towards H. Figure mark: DD.

- A (apex)
- "Orbit. Comet." (the orbit of the comet), along the line through I
- D, K (on the left arc, upper)
- I, L (on the orbit; small circles)
- D, K, F (right of E, at the ends of the dotted lines)
- E (the star), with "Calc." (the Heel) above and "Algol." (Algol) below
- G, H, C, I (on the arc at the foot)
- DD (figure mark)

Diagram. The middle figure, a circle. The horizon M L, the ecliptic, the equator and the orbit of the comet are drawn as arcs. The comet C (a small circle) stands near the top, joined by lines to R and A at the top of the circle and by a dotted line to a third letter beside them; the arc B C D crosses the circle; S stands above the circle, joined by dotted lines to B and A. Caption beneath: "Die 30. Hor. 6 10′ 30″ v." (on the 30th at 6^{h} 10^{m} 30^{s} in the evening). Figure mark: EE.

- S (above the circle)
- R, A (top of the circle), and a third letter beside them, read as E or F [?]
- B (on the circle, upper left), C (the comet), D (on the circle, right)
- Q, P (on the circle, upper right; Q a script capital)
- I, G (joined by a short dotted line), H (on the orbit)
- M, L (ends of the horizon), K (on the horizon)
- N (on the circle, lower left)
- "Ecliptica." (the ecliptic), "Horizon." (the horizon), "Æquator." (the equator), "Oriens." (the east), "Orbita Comet." (the orbit of the comet)
- EE (figure mark)

Diagram. The right figure, a circle. The horizon M I, the ecliptic, the equator and the orbit of the comet are drawn; the star B (marked by a star) with E above it and the comet C (a small circle) with H, W and D below it are joined by straight and dotted lines to each other, and by dotted lines to F and V. on the circle at the right. Caption beneath: "Die 31. Hor. 3 37′ 26″ m." (on the 31st at 3^{h} 37^{m} 26^{s} in the morning). Engraver's signature at the lower right: "Autor ſculp." (the author engraved it). Figure mark: FF.

- A (top of the circle), S (on the circle, upper right)
- Q, P (on the circle, upper left; Q a script capital)
- F, V. (on the circle, right)
- C (the comet), with H, W, D near it
- E, B (B the star)
- M, I (ends of the horizon), K, O (on the horizon)
- N (on the circle, lower right)

- "Calcan. vel Alg." (the Heel, or Algol), "Ecliptica." (the ecliptic), "Æquator." (the equator), "Horizon." (the horizon), "Orbita Comet." (the orbit of the comet), "Occidens." (the west)
- FF (figure mark)

		Therefore the genuine vertical parallax, equated a second time observed on December 30 at $6^h\ 10^m\ 30^s$.	0′ 28½″	For the altitude of the comet 66° 54′ 10″,	

441

But since from this calculation the parallax might perhaps seem to someone too slight, let us therefore go again in search of the same for this same day, and that from other, different observations, namely from computed distances of the comet and the Heel. The earlier, vertical observation was made at $6^h\ 41^m\ 50^s$ on December 30; the later, parallel one is the same one that was used in the preceding investigation. Let us therefore use the preceding figures in turn, and follow the same course of calculation.

[Margin: Eadem parallaxis rursùs inveſtigatur.] *The same parallax is investigated again.*

[Margin: Diſtantia Cometæ & Calc.] *The distance of the comet and the Heel.*

There is no reason for us to seek the later distance, at $3^h\ 37^m\ 26^s$, since it has already been found in the preceding calculation, 12° 46′ 9″, and also corrected and limited; and therefore it is necessary to limit only the earlier distance.

Earlier dist.	12° 12′ 0″	Antil. 2284.304		
Dist. of the Heel from the orb.	1° 6′ 15″	Antil. 18.570 *S.*		
Corrected earlier dist. F L		Antil. 2265.734	12° 9′ 3″ F L	
		The later corrected dist. was	12° 43′ 20″ F I	
		Corrected apparent motion	34′ 17″	
		True proper apparent motion from the tab. for $8^h\ 55^m\ 36^s$	35′ 43″	Hence, since the true proper motion
		is greater than the apparent, therefore the parallax of the orbit is	1′ 26″	

[442] set as above. The marks are printed after the minutes and seconds of the first time, after 20 27 54, 46 56 18, 21 27 0, 23 26, 12 8, 4 43 42 and 77 49 29; the rest are supplied in the house form; no figure is supplied. The sign ♉ (Taurus), the tags *A.* and *S.*, the abbreviations *vesp.* and *m.*, the direction tag *Occ. S.* and the point-letters are the page's own.

443

[Margin: Parallaxis Orbitæ.] *The parallax of the orbit.*

Let us now reduce this to the vertical, after we have computed the azimuth and the altitude of the comet.

The altitude of the comet at 6^h 41^m 50^s in the evening.

Right asc. of the Sun	280° 43′ 0″					
Elong. from the merid.	100° 27′ 30″ *A.*					
Right asc. of the midheaven	21° 10′ 30″	360 degrees cast off.				
Right asc. of the comet	41° 9′ 30″					
Dist. from the merid.	19° 59′ 0″	Log. 107368				
Declin. of the com.	40° 36′ 0″	Ant. 27540 *A.*		Log. 42959		
	C F	Log. 134908	15° 2′ 21″	Ant. 3485 *S.*		Ant. 3485
	Antil. of the altit.	111394 *S.*		Ant. 39474	47° 38′ 0″	
Azim. of the com. *Orient. M.*		Log. 23514	52° 13′ 40″		35° 37′ 0″	
					12° 1′ 0″	Ant. 2216 *A.*
				Altit. of the comet	70° 50′ 12″	Ant. 5701

444

[Margin: Altitudo Cometæ.] *The altitude of the comet.*

For the reduction of the parall. of the orbit to the vertical.

Angle of the orbit and the equat. D H C	63° 10′ 0″	Antil. 79541	
Declinat. D C north	40° 38′ 0″	Antil. 27589 *S.*	
Angle of the orbit and the declin.		Logar. 51952	36° 30′ H C D
Compl. of the elev. of the pole A B	35° 37′ 0″	Logar. 54067	
Azim. L K or S A B	52° 13′ 40″	Logar. 23514 *A.*	
		Logar. 77581	

[443]set as above. The marks are printed after 12 12 0, after 12 9 3 and after the minutes and seconds of the hour; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 34 17, 35 43 or 1 26. The sentence that opens at the right of the sixth line continues at the left of the seventh. The tag *S.* and the point-letters are the page's own.

[444]set unruled, in the page's own columns. The marks are printed after 280 43 0, 15 2 21 and 47 38 0; the rest are supplied in the house form; no figure is supplied. The tags *A.* and *S.*, the direction tag *Orient. M.* and the point-letters are the page's own.

Compl. of the declin. C B	49° 22′ 0″	Logar. 27589 *S.*	
Angle of the vertical and the declinat.		Logar. 49992	37° 20′ B C S or I C D
		Angle of the orbit and the vertical sought	0° 50′ I C G
Mesol. of the side C G, the parall. of the orbit	1′ 26″	778257	
Antil. of the angle of the orb. and the vertical I C G	50′ 0″	11 *S.*	
Mesol. of the parall. reduced to the vertic.		778246	1′ 26″ Mean vertic. parall.

445

[Margin: Parallaxis media.] *The mean parallax.*

But since the angle of the orbit and the vertical is very acute — indeed, the orbit almost coincides with the vertical — the parallax is therefore not changed at all, but remains exactly the same. Nevertheless, because of the later, parallel distance, it must still be equated. This, however, can be done more quickly here, since from the preceding calculation, for the same time, namely 3^{h} 37^{m} 26^{s}, we already have at hand the angle of both the first and the second equation.

For the prosthaph. of the first equation. Subt.

Parall. reduced to the vertical C I or C W	1′ 26″	Log. 778257	
Angle D B C of inclin.	15° 51′ 0″	Log. 129784 *A.*	
Prosth. of the inclin. of the first equat. C W		Log. 908041	0′ 24″ *S.*
		The parall. reduced to the vertical was	1′ 26″
		Therefore the vertical parallax equated a first time	1′ 2″

For the prosthaph. of the second equation. Subt.

Prosthaph. of the inclin. of the first equat.	24″	Mesol. 905886	
Angle W C D	1° 58′ 0″	Antil. 59 *S.*	
Prosth. of the second equat. C D		Mesol. 905827	0′ 24″ Subt.
		The parall. reduced to the vertical was	1′ 26″

445 set as above. The marks are printed after 63 10 0 and after both 1 26, and as column heads over 36 30; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 50 0 or either 1 26. The declination is printed 40 38 0 here and 40 36 0 in the calculation of the altitude above; both stand as printed. The tags *A.* and *S.* and the point-letters are the page's own.

	Therefore the genuine vertical parall., equated a second time	1′ 2″, which is exactly the same
as the parallax equated a first time, so that it does not differ even in the seconds.		For the altitude, that is, of the comet
70° 50′ 12″, observed on December 30 at 6^h 41^m 50^s *vesp.*		

446

[Margin: Parallaxis verticalis ſecundò coæquata.] *The vertical parallax equated a second time.*

Although hardly any other parallax is to be expected for December 30 than the one just found, nevertheless, for the sake of greater certainty, let us examine it further from an observation that is in part different and new and in part already used; and that by means of distances, from the longitudes and latitudes which from the distances observed came out — distances, namely, of the comet and Algol, which are to be computed — since the said fixed star lies very close to the orbit, so that we can leave out the reduction to the orbit entirely and carry out the calculation all the more easily. The earlier observation was made on the 30th at 6^h 10^m 30^s in the evening, in the east, with the comet and Algol standing almost under the same vertical; the later one was taken on the 31st at 4^h 7^m 18^s, in the west, when both phenomena lay in a line roughly parallel to the horizon, and the comet stood only 16 or 17 degrees from the horizon. Just as something unusual, not met with until now, occurs in this later observation, so too it must itself be limited by a particular new method, since the matter is very subtle.

[Margin: Singulari hîc opus eſt limitatione.] *A special limitation is needed here.*

It should be understood, then, that so far no longitudes and latitudes have been used for finding distances in which refraction was neglected, as is clear in the two preceding examples. But in the later observation, of the 31st at 4^h 7^m 18^s, which is now to be used, refraction could not conveniently be applied at the same time, since there the longitudes and latitudes had been derived from distances; let us therefore apply it now. Here, however, it must be noted that both the comet and the fixed star were at that time very low with respect to the horizon, so that their distance from each other was as a result somewhat corrupted by parallax. But if each had stood at an equal distance from the horizon, the refraction of both would certainly have been exactly the same,

[446]set as above. The marks are printed after 1 26 and 0 24 in the first calculation, after 15, after 24, after 1 58 and after 0 24 in the second, and after 70 50 12 and 41 50; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 1 26, 1 2 or 24. The sentence that opens at the right of the fifth line of the second calculation runs on through the two lines below it. The tags *A.* and *S.*, "Subt." and the point-letters are the page's own.

and nothing at all would either have been added to our result or taken from it. For while the comet and Algol are raised equally together, the distance remains the same and uncorrupted. Now, however, since the comet stands somewhat higher, and moreover a far greater refraction belongs to it, as our little table of refraction attests, the distance is noticeably vitiated. It must therefore be restored right at the outset.

[Margin: Animadvertenda.] *Points to be noted.*

On this occasion I also want to remind the reader that in the two preceding investigations, namely 18 and 19, the refraction for the comet was properly observed, since the longitudes and latitudes were derived from the altitudes and azimuths; for the Heel, by contrast, although it was raised only 16° 35′ 30″, that refraction was not applied, so that the parallax may perhaps have been changed as a result by some ten seconds or so [?]. For this reason we will now work out the calculation all the more accurately, so that we may see whether some difference also arises in the parallax on that account.

It is necessary, however, that the calculation be set up again by a new method: first, for the earlier observation, finding both the altitudes and the azimuths of each phenomenon; then the distances of the comet and Algol at each observation — not, indeed, from the complement of the latitude as a side and the difference of longitude as an angle, but from the complement of the altitude and the difference of the azimuths. Above all, however, for the later observation the difference of refraction of the comet and Algol must be at hand, so that you are not unable to subtract it from the altitude of the comet (since the comet is higher than the fixed star), or, what is the same, in this case to add it to the complement of the altitude of the comet; in this way the true, limited later distance may afterwards be drawn out with respect to refraction. This will appear more clearly from the calculation itself, following the course of the earlier diagrams (except that in Figure DD the circles of latitude are circles of altitude, and the ecliptic B C G is the horizon).

[Margin: Calculus iterum novâ methodo inſtituitur, pro die 30 Decembr.] *The calculation is set up again by a new method, for December 30.*

Let us therefore always proceed by this route, as the matter demands, so that not even the smallest thing is neglected, even in the seconds — especially since the parallaxes decrease from day to day and are greatly diminished, just as if they meant to vanish completely all at once.

Investigation of Parallax XX, from the Distances of the Comet and Algol, Computed, for December 30 [Inveſtigatio parall. XX. Ex Diſtantiis Cometæ & Algol ſupputatis, ad diem 30 Decembr.]

450

Since Algol lies almost under the orbit, this parallax needs no reduction to the orbit, but only to the vertical, following the figure E E, and it is completed

449 set as above, Algol's calculation at the left and the comet's from the middle, as on the page. The marks are printed after 281 9 15, 39 37 30, 41 1 29 and 32 22 13, and as column heads over the right 162 59 15, over 31 13 20 and over the left 43 10 58; the rest are supplied in the house form; no figure is supplied. The page prints 162 59 15 for the right ascension of the midheaven, where 281° 9′ 15″ and 241° 49′ 30″, less 360°, give 162° 58′ 45″; and 1 10 30 for the difference of the azimuths, where 43° 10′ 58″ less 42° 0′ 24″ gives 1° 10′ 34″. The printed figures stand. The tags *A.* and *S.* and the point-letters are the page's own.

450 set unruled, in the page's own columns. The marks are printed after 17 38 5, 4 45, 1 7 12, 1 37 11 and the time 9 56 18, and as column heads over 72 24 15; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 2 12, 2 33, 59 44, 37 27, 39 18 or 1 51. The tags *A.* and *S.* and the point-letters are the page's own.

by the shortest route: since the angle of the orbit is vertical [?], it is already established from calculation 18.

Diagram. An engraved figure in a plate-mark, standing at the left of the calculation above and the prose below it. Three arcs descend from A at the top to the horizon drawn across the foot, meeting it at G, C and B; a fourth line from A runs to L. A curve lettered "Orbita Cometæ" (the orbit of the comet) runs down from the upper left through I. D and K stand on the left arc, joined by dotted lines to I and L, which are drawn as small circles. E, a star marked "Algol.", stands on the left arc below K, joined by straight lines to I and L. A further arc lettered "Circuli Altit." (circles of altitude) runs down through L and crosses the horizon near B. "G G" stands between the left and middle arcs above the horizon, and "Horizon." at the left above the horizon line. At the foot stands the engraver's signature, "Aut." with a second word read as [?]culps. (the author engraved it).

- A (top, apex of the arcs): A
- Orbita Cometæ (upper left, along the curve): the orbit of the comet
- D (left arc, upper): D
- I (on the orbit, small circle): I
- K (left arc, below D): K
- L (right, small circle): L
- Algol. (left of E): Algol
- E (star on the left arc): E
- G G (between the left and middle arcs): figure mark G G
- Circuli Altit. (along the right arc): circles of altitude
- Horizon. (lower left, above the line): horizon
- G, C, B (under the horizon line, left to right): G, C, B
- Aut. [?]culps. (foot, right of the middle): the author engraved it

All labels printed on the figure are listed; the first letter of the signature's second word is not settled.

Prosth. of inclin. of the second equat. C D		Mes. 784336 +	1′ 21″ *S.*		
Parall. reduced to the vertical			1′ 52″		
Therefore the true vertical parallax equated a second time			31″		

453

For December 30, at 6^h 10^m 30^s in the evening, with the comet at an altitude of 66° 54′ 10″.

From these results, then, it is clear that the parallax obtained here — although it was investigated from entirely different observations, and also by a very careful method, likewise without neglecting the refraction appropriate to each phenomenon — nevertheless differs by scarcely a very few seconds from the parallax obtained in calculations 18 and 19. So we can be entirely certain and assured of the truth of this parallax.

452 set as above. The marks are printed after 1 10 30 in the first line, and as column heads over 43 46 50, over 73 34 14, over 89 49 6 and over 1 21; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 1 52, 1 21, 14 or 31. The signs + and — and the label *S. Coss.* are the page's own, kept as printed. The tags *A.* and *S.* and the point-letters are the page's own.

453 set unruled, in the page's own columns. The marks are printed after 1 37 11 (both lines), 49 10, 1 10, 43 49 and 1 21 S.; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 1 21, 1 52 or 31. The signs + and the label *S. Coss.* are the page's own, kept as printed. The tags *A.* and *S.* and the point-letters are the page's own.

[Margin: Parallaxinadmodùm exquiſitè eſſe determinatam, ex adeò diverſis inveſtigationibus, luculenter patet.] *That the parallax has been determined very exactly is clearly evident from investigations so different.*

Nevertheless, let us go further and seek the parallax once again for the same day, December 30: namely from the vertical observation of investigation 19 and the parallel observation of investigation 20, and likewise from the distances of the comet and Algol, with the refractions also duly observed, as was done in the preceding inquiry from the complement of the comet's altitude and the difference of the azimuths. But we shall complete this calculation by a much shorter route, since for the later observation there is no need to seek either the altitudes or the azimuths of the comet and Algol, nor to limit the distance, and — what matters most — nor to investigate the angle of inclination of either the first or the second equation. So the true parallax equated a second time can be drawn out very easily with the help of those three preceding figures, D D, E E, F F.

Investigation of Parallax XXI, from the Distances of the Comet and Algol, Computed, for December 30 [Inveſtigatio Parall. XXI. Ex Diſtantiis ſupputatis Cometæ & Algol, ad diem 30 Decemb.]

458

For December 30, at 6^h 41^m 50^s in the evening, with the comet at an altitude of 70° 50′ 12″.

You see, then, that by this day the parallax has diminished remarkably: it now amounts to scarcely as many seconds as it was found to be minutes at the beginning. So it is concluded, not wrongly, that the parallax of our comet will soon, in the days that follow, gradually dwindle and vanish completely. But whether the matter stands entirely so or not, let us inquire with still more examples — namely for December 31, drawing it out from the distances of the comet and Capella. For since this fixed star lies almost at a right angle to the comet and its orbit, and the comet is receding from the fixed star, it can hardly

457 the marks are printed after both 1 22 and after 50 (″ only); the 0 before 50 carries no mark, and both stand as printed. The tag *S.* and the point-letters are the page's own.

458 set as above. The marks are printed after 1 22 in the first line and after each 0 59; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 1 22 or 23. *Subt.* is the page's own, kept. The tags *A.* and *S.* and the point-letters are the page's own.

fail that the parallax comes out still better and more accurately from distances of this kind than by the true and apparent motion.

[Margin: Parallaxis plùs plùsq́; attenuatur.] *The parallax is reduced more and more.*

463

[Margin: Figura H H.] *Figure H H.*

[Margin: Differentia Diſtantiarum.] *Difference of the distances.*

Since, however, this later distance, corrected and limited, is smaller than the earlier distance — although it was determined exactly, with the angle of the orbit and the point of intersection — whereas, on the contrary, that later distance ought to have been larger on account of the parallax. For at that time the comet was below Capella, and at the same time on one and the same vertical; and there, necessarily, if any parallax had been present, that distance would have appeared increased, according to axiom 5, p. 227.

Therefore no parallax any longer attaches to this observation, made on the 31st at $4^h\ 7^m\ 18^s$ with the comet at an altitude of 17° 18′ 5″; or at least no perceptible parallax can be inferred from these observations.

[Margin: Die 31 Dec. nulla ſenſibilis parallaxis Cometæ adfuit.] *On December 31 the comet had no perceptible parallax.*

But, you will say, what if something lies hidden in the refraction? For the larger the refraction applied to the comet, the larger too the parallax that comes out. This we certainly cannot deny at all. But whether or not some parallax underlies it here, we shall find out at once, by applying, namely, Tycho's refraction of the Moon to the later distance, for the limitation, so that it may become fully clear what is to be concluded on this matter altogether.

[Margin: Aliâ diverſâ indagine iterum tentatur, an aliqua hîc lateat parallaxis ?] *It is tested again, by another and different inquiry, whether some parallax lies hidden here.*

464

Nevertheless, although the greatest refraction of all, namely Tycho's refraction of the Moon, was applied here, the later distance still came out smaller than the earlier by 7″. Therefore, according to axiom 5, there is no parallax in these observations for December 31; or at the very least none perceptible is detected.

[Margin: Parallaxis evaneſcere videtur.] *The parallax seems to vanish.*

But let us inquire further, with the help of other observations of December 31, whether there is any parallax at this time; and again partly from computed and partly from observed distances of the comet and Capella. First, namely, from the distance of the comet and Capella observed on the 30th at $6^h\ 41^m\ 50^s$, and from the other, later one, computed in the preceding calculation for $4^h\ 7^m\ 18^s$ on the 31st, so that any parallax that is present will show itself at once and with no great labour. For there is no need to compute the first distance, since it was observed. Indeed, even if you computed it from the altitudes at $6^h\ 41^m\ 10^s$ in the evening, it would still come out exactly the same, namely 23° 27′, as could easily be shown by the calculation itself, if we did not wish to spare paper.

[464] set unruled, in the page's own columns. The marks are printed after 72 21 55, 17 18 5, 23 37 25 (the first), 37 56 (′ ″) and 10 16 (′ ″); the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 6 51, 37 56, 10 16 or 7. The page prints 6.534, 8622.222, 6.088, 0.446 and 8628.310 with points, kept. *Add.* is the page's own, kept. The tags *A.* and *S.* and the point-letters are the page's own.

Investigation of Parallax XXIII, from the Distances of the Comet and Capella, One Observed and the Other Computed and Limited by Refraction, for December 31 [Inveſtigatio Parallaxeos XXIII. Ex diſtantiis Cometæ & Capellæ, alterâ obſervatâ alterâ ſupputatâ, ac per refract. limitatâ Ad diem 31 Decemb.]

1 Obs. at the hour	$6^h\ 41^m\ 50^s$	Dist. of the comet and Capell., observ.	23° 27′ 0″ Parall.
2 Obs. at the hour	$4^h\ 7^m\ 18^s$	Dist. of the comet and Capell., computed, and limited by our refract., 4′ 45″, p. 257.	23° 25′ 56″ Vertic.
		Different.	1′ 4″

465

The later distance is therefore smaller than the earlier: so, according to the often-cited axiom 5, there is no parallax in the observations. But let us apply Tycho's refraction of the Moon, to see whether some parallax can be drawn out in this way.

Earlier distance, observed	23° 27′ 0″	
Later distance, limited by the refract. of the Moon, 6′ 51″	23° 27′ 38″	
Difference of the distances, or parall.	38″	fictitious.

466

Since, then, the later distance is larger than the earlier by 38″, some parallax, however very slight, certainly lies hidden here. This fictitious parallax should therefore be reduced to the vertical. For this we need both the altitudes and the azimuths, of the comet as well as of Capella, for the later observation, made at $4^h\ 7^m\ 18^s$, which have already been found in the preceding calculations.

[Margin: Parallaxis ad vertical. reducta.] *The parallax reduced to the vertical.*

To find the prosthaphaeresis of inclination for the earlier observation, which was parallel to the horizon, we must compute the angle of inclination D B C, again with the help of the altitudes and azimuths. The comet's altitude and azimuth are indeed already given in investigation XIX; but those of Capella must now first be determined, namely for the hour $6^h\ 41^m\ 50^s$, following the construction of the diagram C c above.

469

At the comet's altitude of 17° 38′ 5″, on December 31 at 4^h 7^m 18^s in the morning. Which was to be investigated.

Although it is clearly established from these two inquiries, made for December 31, that the parallax was very slight (for from calculation XXII none at all came out, and from this one, XXIII, a parallax of only 18″, at an altitude of about 17°), let us nevertheless pursue it more and more, from other, different observations, to see whether the matter really stands so. For in these last days of the apparition both skill and labour certainly failed in determining the parallaxes correctly by calculation: not only because they amounted to mere seconds, but above all because the comet was becoming smaller, fainter and lower, frequent changes of the air intervened, and, what matters most, it was not granted to observe it with suitable instruments in both quadrants.

[Margin: Quare ultimis diebus artis fuerit parallaxes rectè explorare.] *Why, in the last days, it was a matter of skill to determine the parallaxes correctly.*

Investigation of Parallax XXIV, from the Computed Distances of the Comet and Capella, Namely from the Altitudes and Azimuths, for December 31 [Inveſtigatio Parall. XXIV. Ex Diſtantiis Cometæ & Capellæ ſupputatis, & quidem ex altitud. & azimuthis, Ad diem 31 Decembris.]

Prosth. reduced to the vertical	3′ 13″
Therefore the genuine vertical parallax equated a second time	1′ 8″

478

For December 31 at 3^h 37^m 26^s in the morning, with the comet at an altitude of 20° 27′ 54″.

[Margin: Parallaxis genuina, ad d. 31 Decemb.] *The genuine parallax, for December 31.*

Even though I am entirely certain that hardly any refraction other than the one assigned to it in the small refraction table applies to our comet, let us nevertheless work through this example too with the help of Tycho's lunar refraction: both so that it may be clear how much larger the parallax turns out, and so that no one may fail to see that, even with this refraction applied, the whole parallax can still hardly grow beyond 2 minutes.

This inquiry, however, will be carried out very easily this time, since only some parts of the earlier calculation change, while all the rest serve this one equally. So the earlier distance of the comet and Capella, for the hour 6^h 10^m 30^s, is kept; the later one, however, changes slightly by reason of the parallax, and consequently so do the angle F I E and likewise the fictitious parallax. But in the reduction to the vertical the same angle E C D remains, and so does the angle of the prosthaphaeresis of both the first and the second equation.

Investigation of Parallax XXV, from the Computed Distances of the Comet and Capella, Namely from the Altitudes and Azimuths, for December 31 [Inveſtigatio Parallaxeos XXV. Ex diſtantiis Cometæ & Capellæ ſupputatis & quidem ex altitud. & azimuthis, Ad diem 31 Decemb.]

1 Obs. d. 30 at	6^h 10^m 30^s	Distance of the comet and Capella	23° 28′ 5″	Parall.

Diagram. An engraved figure within one plate mark, with two drawings side by side. On the left, a spherical triangle with its apex A at the top and its base along the ecliptic; a star E on its left side is joined by straight and dotted lines to points near the right-hand arcs, and the comet's orbit is drawn as a line through two small circles. On the right, a circle crossed by the ecliptic, the equator, the horizon and the comet's orbit, with Capella marked as a star at E and the comet at C. Below the circle the plate carries an engraved date line and the engraver's note.

- A (apex of the left triangle): A
- inside the left triangle: H h (the figure's own designation)
- along the orbit line, upper part: Orbit [Orbita]
- along the same line, lower part: comet [?] (the ending of the word not read)
- points on the left drawing: M, L, D, K, E (a star), F
- along the base arc: Ecliptic [Ecliptica.]
- on the base arc: G, H, C, B
- on the rim of the circle: A (top), F, S, R, L, N, M, P
- at the end of the ecliptic line, above P: [?] (a glyph of a loop over an open curve, not read)
- along the line from P: Equator (its engraved initial not separated between Æ and A)
- beside the star E: Capella
- along the line through E: Ecliptic [Ecliptica.]
- along the line from M to L: Horizon [Horizon.]
- along the lower line: Orbita Cometæ.]
- in the lower part of the circle: West [Occidens.]; I i (the figure's own designation)

[480] set unruled, in the page's own columns. The marks are printed after 69 32 6, 20 27 54 and 23 42 25; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 5 15. The tag *A.* and the point-letters are the page's own.

- points inside the circle: E, D, I, G, C (a small circle with a point), K, O
- engraved line below the circle: On January 1 at 3^h 26^m 0^s in the morning [Die 1 Ian. Hor. 3 26′ 0″ m.]
- engraved at the lower right: The author engraved it [Autor ſculps.]

Labels not read: the glyph above P, and the ending of the word along the left orbit line.

For the angle F I E, and for eliminating the proper motion.

		Therefore the genuine vertical parallax equated a second time	2′ 8″

484

For December 31 at 3^h 37^m 26^s, with the comet at an altitude of 20° 27′ 54″.

[Margin: Quanta fuerit omnium maxima ad diem 31 Decemb.] *How great the largest of all was, for December 31.*

This, then, is the largest parallax of all that we have been able to derive for this December 31, although I am entirely of the opinion that hardly so great a one really existed at that time, as all the remaining investigations attest. So let whatever has been explored for this day, December 31, suffice; and let us at last turn to January 1 of the year 1653, making an effort to be able to explore the parallax of this day too. It will certainly be very difficult to investigate, both for the reasons given above and because no genuine vertical parallax can be investigated from our observations, but only the difference of the parallaxes between 22 and 20 degrees of the comet's altitude. Nevertheless it will be more

[483]set as above. The marks are printed after 6 2 (the first) and 3 46 (′ ″); the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 6 2, 3 46 or 2 16. *Subtr.* and the caption's Subt. are kept unexpanded, as printed. The tag *A.* and the point-letters are the page's own.

[484]set unruled, in the page's own columns. The marks are printed after 3 46 and 3 54 (′ ″); the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 3 46, 3 54, 6 2 or 2 8. *Subtr.* is kept unexpanded, as printed. The tag *S.* and the point-letters are the page's own.

than sufficiently clear that the horizontal parallax of January 1 amounted to hardly, if even hardly, one whole minute.

First, let us set up the calculation from the distances of the comet and Capella; then from the distances of the comet and the bright star in the side of Perseus — and namely from longitudes and latitudes still to be computed, since at the time of observation only altitudes and azimuths were observed. Both observations, moreover, were made in the same western quarter, the earlier at $3^h\ 26^m\ 0^s$ and the later at $3^h\ 44^m\ 16^s$ in the morning; and both, too, almost under the same vertical. Here it should be noted that this time there is no need of refractions, since they have already been applied in the case of the longitudes and latitudes.

Investigation of Parallax XXVI, from the Computed Distances of the Comet and Capella, for January 1 [Inveſtigatio Parallaxeos XXVI. Ex diſtantiis Cometæ & Capellæ ſupputatis, ad diem 1 Januarii.]

1 Obs. d. 1 January, at	$3^h\ 26^m\ 0^s$ *man.*	alt. of the com.	21° 57′ 0″	azim.	46° 10′ *Occ. S.*	Vertical.

[Margin: Parallaxis ficta.] *Fictitious parallax.*

Now, for reducing the parallax to the vertical, let the altitude and azimuth of Capella first be sought for each observation. Then from these, and from the altitudes and azimuths of the comet, let the angle E C D be sought — in the preceding Figure H h, the angle enclosed by the vertical circle A C and the line of distance E C — so that by means of this angle the parallax reduced to the vertical may come out.

For the altitud. of Capel. at 3^h 26^m 0^s

488 set unruled, in the page's own columns. The marks are printed after 17 0 12, 29 0 40, 22 38 29, 24 4 50 and the 180 of the compl. label; the rest are supplied in the house form; no figure is supplied. 492

[Margin: Differentia parallaxium nondum duorum ſecundorum.] *The difference of the parallaxes not yet two seconds.*

It is therefore clear that this difference of the parallaxes is hardly perceptible, since it is only 1″ 23‴. So let us once more, as we have already indicated, seek the same difference of the parallaxes through the distances of the comet and the bright star in the side of Perseus, to see whether the same will come out here too. Since this fixed star likewise lies at roughly a right angle to the comet and its orbit, the operation is plainly the same as the earlier one, except that in this example the comet was approaching the bright star in the side of Perseus, whereas in the preceding inquiry it was receding from Capella. Hence it is not the later but the earlier distance that has to be corrected for the equation, although it appears smaller; for in the later distance the difference of the parallaxes really lay hidden. For that reason, too, the figures have to be changed.

Investigation of Parallax XXVII, from the Distances of the Comet and the Bright Star in the Side of Perseus, Computed for January 1 [Inveſtigatio Parall. XXVII. Ex Diſtantiis Cometæ & Lucid. later. Perſei ſupput. ad diem 1 Januarii.]

[Margin: Diſtantia fixæ ab orbitâ.] *Distance of the fixed star from the orbit.*

Diagram. An engraved figure across the measure, with two drawings side by side. On the left, a narrow spherical triangle with its apex A at the top and its base along the ecliptic; the star at E, labelled as the bright star in the side of Perseus, is joined by dotted lines to D and to a small K, and by straight lines to two small circles near the arcs; a line labelled as the comet's orbit crosses the arcs from A. On the right, a circle crossed by lines labelled the ecliptic, the equator, the horizon and the comet's orbit, with the labelled star at E and a small circle at C. Below the circle the plate carries an engraved date line and the engraver's note.

[495] set as above. The marks are printed after 20 43 42, 25 49 58 and 5 26 27; the cell ° ′ ″ is the page's own; the rest are supplied in the house form; no figure is supplied. The sign ♉ is the page's own; *Bor.* is kept unexpanded, as printed. The tags *A.* and *S.* and the point-letters are the page's own.

[496] set unruled, in the page's own columns. The marks are printed after 27 1 12, 6 25 49 and 67 6 45; the cell ° ′ ″ is the page's own row of marks over the arc column below it; the rest are supplied in the house form; no figure is supplied. The sign ♉ (Taurus) is the page's own. The tags *A.* and *S.* and the point-letters are the page's own.

502

[Margin: Differentia parallaxeos adhuc minor prodit.] *The difference of the parallax comes out still smaller.*

It is therefore apparent from this inquiry that this difference of the parallax comes out still a little smaller, only 16‴, so that it now vanishes entirely.

Finally, I would very gladly go further in the task we have undertaken, inquiring also whether any parallaxes are to be found for January 2, 3, 4 and 7. But in truth, however much I might wish it, it is still not possible to derive this from the observations of those days. For at that time, because of various obstacles, no observations of the kind required were obtained with suitable instruments, either the azimuthal quadrant or the sextant. And although on January 4 and 7 one or another observation of the comet was made with the sextant, yet, because the comet was then very faint, diminished in body, and also wrapped in refractions, those observations were not carried out accurately enough; hence nothing at all certain is promised from them either. It is better,

[501] set side by side on the page, the first hour at the left and the second at the right. The marks are printed after 1 25 40 and 1 33 26; the rest are supplied in the house form; no figure is supplied. "The star" renders the page's star sign. The tags *A.* and *S.* and the point-letters are the page's own.

[502] set side by side on the page, the first hour at the left and the second at the right; the lines below the right half run on under it, and the dash and the 16 stand on the line of the earlier altitude, under the columns of the reduced parallaxes. The marks are printed after 1 8 at the left (′ ″) and after 1 8 at the right, where the mark after the 1 is the degree mark (° ″); each cell ′ ″ ‴ is the page's own row of marks over the column below it; the mark is printed after 21 57 0; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 1 8, 1 9 8, 1 9 24 or 16. The tag *S.* and the point-letters are the page's own.

therefore, to pass over those observations, to stop at this first day of January, and to rest content with the parallaxes investigated by the method kept above — as indeed there is no one who may not rightly rest content with them: with those, namely, that were drawn out in the very extensive calculation above, with the greatest labour, greater indeed than you will perhaps believe.

[Margin: Quare parallaxis ad dies ſubſequentes Januarii, inveſtigari haud potuerit.] *Why the parallax could not be investigated for the following days of January.*

In future, however, when we undertake to examine the parallaxes by another method, we shall take pains that something certain may be drawn out for January 4, above all from the apparent and true altitudes of the comet. Without any doubt, though, just as on December 31 and January 1 all parallax was almost imperceptible, so too on the 4th we shall find hardly a trace of parallax.

[Margin: Autor exiſtimat Cometam die 4 Januarii nullam prorsùs posſedisſe parallaxin.] *The author judges that on January 4 the comet had no parallax at all.*

Before we come to the remaining methods of examining parallaxes, it will not be out of place to compute in advance, from each of the vertical parallaxes found above, the horizontal parallaxes, and to enter them in a table of their own. By their means it will become much clearer still to anyone how matters stood with those parallaxes, and in what way they decreased continuously from day to day. Moreover, you will also form from this a sounder judgement of what is to be decided about our observations, and about the method of calculation itself. Certainly anyone who examines the matter with a fair balance will marvel that almost all the operations agree so accurately, and at how we could have reached such precision: above all if one rightly weighs what it cost to obtain so many suitable observations from the sky itself — and that in such a comet, whose head was of rare size at the beginning and very small at the end, whose motion was very swift, but which was endowed with feeble light, and then was mostly very near the horizon and exposed to refractions, so that it could scarcely be seen with the naked eye, and by rather few.

[Margin: De parallaxibusCometæ horizontalibus.] *On the horizontal parallaxes of the comet.*

It would indeed not have been so hard to carry out observations of certain new stars and to derive parallaxes from them, since most of them abound in vigorous light and lack all motion whatever. So I cannot wonder enough how it came about that some mathematicians in the year 1572, in their observations of that new and by far most splendid star in Cassiopeia, could err so enormously. For either they lacked suitable and very large instruments, or the observers themselves are wholly to be accused of negligence: for in the space of about 15 months (so long did it stand constantly visible in the sky) they observed nothing certain and worth noting, as Tycho has sufficiently shown.

[Margin: Longè operoſius eſt, diverſitatem adſpectus in Cometis, quàm in novis Stellis deprehendere.] *It is far more laborious to detect the parallax in comets than in new stars.*

[Margin: Rationeparallaxeos circa novam Stellam 1572 nonnulli enormiter aberrarunt.] *In respect of the parallax, some erred enormously concerning the new star of 1572.*

Besides, it would have been far less work if I had chosen to investigate the parallaxes in the way that Brahe used for the comet of the year 1577 and Cysatus [Johann Baptist Cysat] for the comet of the year 1618. For neither of them, in even a single example of calculation, displayed to us demonstratively the pure vertical parallax of some definite altitude; instead they gave the difference of the parallax of two altitudes, and only as probable. [Margin: Faciliùs more Tychonico parallaxes inveſtigare.] *It is easier to investigate parallaxes in Tycho's manner.* Moreover, Tycho was never concerned, much less Cysat, that Scheat and the Mouth of Pegasus (from which they counted the distances) stood about 4, 5 or 6 degrees from the comet's orbit. And they took no account at all of whether the comet and the fixed star stood under one and the same vertical, or under very different verticals and at a very evident angle: indeed, even when, as mostly happened, they lay at an angle of 30 or 40 degrees, they still used no limitation or reduction at all. [Margin: Quâ ratione Tycho & Cyſatus parallaxes deduxerint.] *How Tycho and Cysat derived the parallaxes.* Hence, in that way, the difference of the parallaxes is indeed derived as probable by the mathematicians named above much more readily than the genuine vertical parallax of the comet is explored by us demonstratively, from almost every calculation; but, on the other hand (which I would wish said without prejudice to their reputation), their parallaxes did not come out so accurately: for, as is easily gathered, it was very easy for them to stray by one or two minutes. It would therefore have been better, in my judgement at least, if Tycho had chosen, for computing the parallaxes, fixed stars either nearest to the orbit, or placed at about a right angle to the comet and its orbit: for instance, the left hand of Antinous, the one in the head of

Equuleus, and above all Scheat (which star, with the comet, mostly stood in the earlier observation at a distance parallel to the horizon, and in the later observation vertical), and had carried out the calculation by our method. But since this method of ours for deriving parallaxes was not yet known at that time, and Tycho, besides, was hindered by other, weightier business and observations, he is easily excused here.

If this were the place for it, I would show how the genuine vertical parallaxes of the comet of the year 1577 can be examined from Tycho's own observations; but this business, as foreign to the matter, must be put off to another occasion. Let us return, then, to computing our horizontal parallaxes from whatever parallaxes of altitude were found above, so that it may be all the more evident in what way they changed and diminished continuously from December 23 to January 2, before we go on to examine the parallaxes by another, different method, as we promised at the beginning of this Book IV. But to save time, let us show by a single example only, from the first investigation, by what method these horizontal parallaxes were obtained, and let us enter the rest in a small

table, with all calculation omitted. Let the logarithm of the complement of the altitude, then, be subtracted from the logarithm of the parallax of the given altitude; from the remainder you will have the logarithm of the horizontal parallax sought. For example:

[Margin: Ex obſervationibus quoq́; Tychonianis parallaxes verticales Cometæ anni 1577 erui poſſunt.] *The vertical parallaxes of the comet of the year 1577 can also be drawn from Tycho's observations.*

[Margin: Ratio inveſtigandi parallaxes horizontal.] *The method of investigating horizontal parallaxes.*

In the first investigation the parall. of altitude was found for the altit. 44° 28′;

Its compl., namely	45° 32′ 0″	Logar. 33735 *S.*	
Parall. of the altit.	17′ 2″	Logar. 530740	
Parall. horizont. sought		Logar. 497005	23′ 52″

503

In this way all the rest were computed, whatever the following small table contains. Its first column shows the order of the investigations; the second, from which distances the parallaxes were computed, whether from observed or from computed ones; the third, on what day and month, and the fourth, at what hour, minute and second the observations were taken; the fifth, at what altitude the comet then stood; the sixth shows the parallax of altitude found, and the seventh the horizontal parallax.

Horizontal parallaxes of the com. of the year 1652, derived from the parallaxes of altitude found above.

[Margin: Parallaxes horizontales Cometæ an. 1652] *Horizontal parallaxes of the comet of the year 1652.*

[Margin: Differentia Parallaxium.] *Difference of the parallaxes.*

From this table it is clear how the parallaxes of our phenomenon decreased from day to day, keeping a definite proportion, so that on about December 31 or January 1 they vanished almost entirely. [Margin: Initio Januarii parallaxis omninò evanuit.] *At the beginning of January the parallax vanished entirely.* But while you consider everything somewhat more deeply, weigh each of the investigations of the parallaxes carefully, and above all pick out the more certain parallaxes from the rest, which are less certain, you will find that on December 23 the horizontal parallax was scarcely 30 min., indeed somewhat less;

just as can be shown by four examples that agree almost to the very minutes: that on the 26th, in the evening, it did not exceed 19′, or 20′ at most; on the 27th, in the evening, it was scarcely 8′ or 9′; on the 28th, scarcely 5′ or 6′; on December 30, 2′ or 3′; on the 31st, 1′ at most; and on January 1 it was already imperceptible. From these, in their own place and time, for which they

[505] the table of p. 336 continues with its seven column heads set again, and no caption. Each entry stands on two printed lines, kept here as two rows. The third and fourth columns share one printed head, "At what time they were taken". In entries 7, 10–14 and 26–27 one date stands for both lines; in 9 and 15–25 the page prints two day numbers with one month name between them. In entries 7–25 the cells carry no marks, and the marks are supplied in the house form, after the units the heads print; in entries 26 and 27 the page itself prints ″ and ‴ over the two figures of the parallax of altitude, and leaves the last column blank. Entry 22 prints a single 0 in each parallax cell. The page writes the star of entries 8 and 13 with the sign ♈ (Aries). *v.* and *m.* are the page's own tags on the times, kept unexpanded; in entry 12 no point is seen after the second time's tag. No figure is supplied.

are reserved, we shall be able to derive demonstratively the true distance of the comet from the Earth that belongs to each day of the apparition. Before we undertake that, however, we shall investigate the parallaxes further, to see whether they really were as large as this or not, and indeed by the three different methods that follow.

[Margin: Diversâ methodo parallaxes inquirantur.] *Let the parallaxes be investigated by a different method.*

Now, then, let us first compute the vertical parallaxes by means of the apparent and the true altitudes, from certain observations suited to this business; for they cannot be derived from each and every one. For if the comet's apparent altitudes are either too near the meridian or remote from it, and likewise if the comet's azimuth was either too large or small, misshapen triangles are formed, so that the calculation cannot always agree even in the minutes themselves, let alone in the seconds. And hence it is most certain, as we have often said already, that the parallaxes can in no way at all be investigated from any and every observation, however supremely accurate, whatever method is adopted; rather, one must weigh carefully which observations suit this or that calculation. Otherwise you will surely labour in vain.

[Margin: Methodus Tychonis probabiliter tantùm parallaxes commonſtrat.] *Tycho's method shows the parallaxes only as probable.*

This method of ours, by the altitudes, will show the genuine parallaxes more truly than Tycho's, which its author himself mentions in book II on the comet of the year 1577, p. 134. For that method establishes only as probable that the comet moves above the Moon; ours, by contrast, exhibits the true vertical parallax of any given altitude, and consequently shows demonstratively the genuine distance from the Earth.

[Margin: Quid ſit parallaxis verticalis.] *What the vertical parallax is.*

For it is established from the doctrine of parallaxes that the vertical parallax is nothing but the difference between the apparent and the true place of the phenomenon, reckoned in the circle of altitude [circulus altitudinis], or vertical circle. Therefore, when the apparent and the true altitude of the comet are given together, their difference too becomes known, namely the pure vertical parallax sought itself. But you ask where these data are to be drawn from? I shall tell you: the apparent altitude from the observation; the true one, however, is elicited only by calculation, given, namely, the true declinations, right ascensions, longitudes and latitudes, which are to be taken from the table of the comet's true motion, or Ephemeris, constructed for each day of the whole apparition and for their quarters, and inserted at Sect. XI, Book I, p. 129. On what foundations these true motions of the comet were computed is set out in almost the whole of Book I, to which I refer the reader.

[Margin: Parallaxium calculus ex altitudinibus.] *Calculation of the parallaxes from the altitudes.*

Now I hasten to the calculation itself. Let the vertical parallax be sought, then, for December 24, in the morning, at $1^{h}\ 44^{m}\ 15^{s}$, at which time the apparent

altitude of the comet was observed to be 30° 53′ 0″. Let its true altitude for the same time be computed, given, namely, the right ascension of the Sun and the elongation from the meridian, and also the true declination and right ascension of the comet, taken from our Ephemeris just mentioned, but with the proportional part properly applied, wherever it is needed. Then from the true altitude found (which is always greater than the apparent one) let the apparent observed altitude be subtracted, and indeed after it has first been properly limited for refraction, if the comet's position so requires. The remainder is the pure vertical parallax at that same apparent altitude.

There is no need to say much about setting up the calculation itself, since enough has already been said above, at length and in several places, about finding the altitudes. So only the bare calculation will be given, with some necessary diagrams.

Diagram. An engraved figure across the measure: three circles side by side, each crossed by lines labelled as the ecliptic, the equator, the horizon and the comet's orbit, with a small circle at C marking the comet, a pair of letters inside, and an engraved line under it naming the calculations it serves. The left edge of the first circle runs into the gutter and is not seen.

- First circle, upper left: [?] (a looped sign, a script Q or an 8), and F
- First circle, top: A; upper right: S, G
- C (at the small circle, a dotted line from it up to F): C
- Along the line through C: Orbit. Cometæ — *orbit of the comet*
- Left: I
- Along the horizon line: Horizon. — *horizon*; L at its right end; O at the foot of an arc on it
- Along two lines descending to the right: Æquator. — *equator*; Ecliptica. — *ecliptic*; T and N at their ends
- Inside, lower left: MM
- Under the first circle: Pro Calculo 1; 2, 3. — *For calculations 1, 2, 3*
- Second circle, top: G, A; upper right: F (a dotted line from it down to C); upper left: S
- C (at the small circle): C
- Along a line rising to the right: Ecliptica. — *ecliptic*
- Right: I
- Ends of the horizon line: M (left), L (right); along it: Horizon. — *horizon*; O at the foot of an arc on it
- Lower left: Æquator. — *equator*
- Written upward along the line through C: Orbit. Comet. — *orbit of the comet*; X at its foot
- Inside, lower left: NN
- Under the second circle: Pro Calc. 4,5,6,7. — *For calcs. 4, 5, 6, 7*
- Third circle, top: A; upper right: S
- Along two lines descending to the right: Ecliptica. — *ecliptic*; Æquator. — *equator*

- C (at the small circle, a dotted line from it to F at the right): C, F
- Along the horizon line, left: Horizon. — *horizon*
- Along the orbit line: Orbita (at its left end) and Cometæ. — *orbit of the comet*
- O (at the foot of an arc from S): O; lower right: I
- Inside, lower left: Oo
- Under the third circle: Pro Calc. 8,9,10,11,12 — *For calcs. 8, 9, 10, 11, 12*
- Engraver's note: Autor fculps. — *The author engraved it*[506]

Calculation of the Parallaxes I, for December 24, at 1^h 44^m 15^s in the morning.

Right asc. of the Sun	273° 16′ 42″					
Elong. from the M.	206° 3′ 45″ *A.*					
Right asc. of the midheaven	119° 20′ 27	360 degrees cast off				
Right asc. of the comet	56° 49′ 44″					
Dist. from the merid.	62° 30′ 43″	Log. 11977				
Declin. of the com.	19° 0′ 4″	Ant. 5603 *A.*	° ′ ″	Log. 112212		
		Log. 17580	57° 0′ 57	Ant. 60796 *S.*	° ′ ″	Ant. 60796

Calcul. of the Parall. X, for January 1, at 3^{h} 26^{m} 0^{s} in the morning.

[508] the page sets the five calculations unruled, in its own columns, and side by side, as on the page before: each begins at the left and continues at the right beside the opening of the next, and the eighth ends at the right below. Each calculation is given here as one block, its rows in the order printed. The marks are printed after the Sun's right ascensions, the times of the captions and the 360 of the seventh calculation; in the eighth the sort after 281 is not separated between a degree mark and a small a; the cells ° ′ ″ are the page's own rows of marks, printed in the fourth, fifth and sixth calculations only; the rest are supplied in the house form; no figure is supplied, and no degree figure stands before 7 40, 9 13, 5 33, 4 33 or 5 50. The tags *A.* and *S.* are the page's own; the fifth calculation's antilogarithm 1125 carries none, and the eighth's elongation none.

[Margin: Parallaxis diei 4 Januarii.] *Parallax of January 4.*[509]

From these twelve very different investigations it is clearly evident of what kind and how great the comet's vertical parallaxes come out by the method just set out: namely, that they agree quite precisely with the others, derived from the distances.

And although they might at times disagree by a minute or so, it would still not follow from this that the comet did not remain in the highest aether, as we have proposed to say more fully below, in its proper place; especially since the parallaxes just found turn out to be somewhat smaller still than the earlier ones. But so that anyone may judge this very point the more accurately, as if at a single glance, we shall likewise compute the horizontal parallaxes from these parallaxes of altitude and, leaving out all the calculation, enter them in the table adjoined.

Vertical and Horizontal Parallaxes of the Comet, derived from the apparent and true altitudes.

Calculation	At what time they were taken by observation: Day, Month	Hour, Min., Sec.	Altitudes of the comet (Deg., Min., Sec.)	Parall. of altitude (Min., Sec.)	Horizontal parall. (Min., Sec.)
1.	December 24	$1^h\ 44^m\ 15^s$ *m.*	30° 53′ 0″ apparent	22′ 11″	25′ 51″
			31° 15′ 11″ true		
2.	December 26	$11^h\ 44^m\ 48^s$ *v.*	51° 36′ 15″ apparent	5′ 5″	8′ 11″
			51° 41′ 20″ true		
3.	December 26	$11^h\ 50^m\ 31^s$ *v.*	50° 44′ 0″ apparent	9′ 13″	14′ 34″
			50° 52′ 55″ true		
4.	December 27	$5^h\ 14^m\ 5^s$ *v.*	49° 51′ 0″ apparent	7′ 40″	11′ 54″
			49° 48′ 40″ true		

[509] the page sets the four calculations unruled, in its own columns, and side by side, as on the pages before: each begins at the left and continues at the right beside the opening of the next, and the twelfth ends at the right below. Each calculation is given here as one block, its rows in the order printed; the short blocks of apparent altitude, refraction and corrected altitude that stand at the right beside the openings of the ninth, tenth and eleventh calculations are set in the rows beside which they stand, and in the eleventh the two such blocks, our own refraction and Tycho's, stand side by side, as on the page. The sentence of the tenth calculation is printed after its last altitude and runs on below it; that of the eleventh likewise, ending with an apparent and a corrected altitude and a 0 below them. The marks are printed after the Sun's right ascensions, the times of the captions, the apparent altitudes of the tenth and eleventh calculations' refraction blocks and the 360 of the eleventh; in the twelfth the mark after the Sun's 31 is double, as printed; the cells ° ′ ″ are the page's own rows of marks; the rest are supplied in the house form, and the point printed after the ninth calculation's 27 is not carried. No figure is supplied, and no degree figure stands before 3 30, 2 25, 5 28, 5 30 or 14. The tags *A.* and *S.* are the page's own; the eleventh calculation's refractions carry none; the 0 that closes the eleventh is followed by a mark that is not settled.

Cal-cula-tion	At what time they were taken by observation: Day, Month	Hour, Min., Sec.	Altitudes of the comet (Deg., Min., Sec.)	Parall. of altitude (Min., Sec.)	Horizontal parall. (Min., Sec.)
5.	December 27	$5^{h}\ 23^{m}\ 58^{s}$ *v.*	51° 16′ 0″ apparent	9′ 13″	14′ 44″
			51° 25′ 13″ true

[Margin: Parallaxes Verticales & horizontales Cometæ 1652.] *Vertical and horizontal parallaxes of the comet of 1652.*

From these very many investigations, then, about 40 in number, made by the distances as well as by the altitudes, I believe that everyone who loves the truth now gathers more than enough to see how matters stand, all in all, with the true parallaxes of our comet; and that, from these horizontal parallaxes, they amply suffice both to demonstrate in due course to all the Peripatetics the true distance of the comet from the Earth, for any day of the whole apparition as well, and to settle completely those very bitter disputes among those of whom some contend that the comet is aethereal and others that it is sublunary. But to fulfil our promise, and to give this matter more and more satisfaction, let us

510a ruled, boxed table of six columns under a caption. The head "Quo tempore observat. fuerint habitae" runs across the day column and the time column; the unit rows (Day, Month; Hour, Min., Sec.; Deg., Min., Sec.; Min., Sec.) are the page's own, set in the house form in the cells. Each calculation takes two printed lines, the apparent altitude above and the true below, with the number, date, time and both parallaxes standing between them; they are given here as two rows, with those cells in the first. The row numbers 1–6 carry a point and 7–12 none, as printed; the time tags *m.* and *v.* are the page's own; the figures 0 before 14 and 16 in the last row, and every 0 in rows 10 and 11, are printed; no figure is supplied.

examine those parallaxes in yet another way, namely from the apparent and true declinations and latitudes. How this investigation ought to be set up must now be told; for, as far as I know, it has not until now been sufficiently discovered.

[Margin: Vera diſtantia Cometæ à Terrâ abundènunc demonſtrata eſt.] *The true distance of the comet from the Earth has now been amply demonstrated.*

[Margin: Deparallaxibus ex declinationibus & latitud. erutis.] *On parallaxes derived from the declinations and latitudes.*

Just as the difference between the true and the apparent place in the vertical circle shows the vertical parallax itself, so likewise the true and the apparent declination show the same parallax: namely when, as happened in our phenomenon, its orbit intersects the equator and the ecliptic at a fairly obtuse angle, that is, when the comet is carried by its proper motion roughly either from south to north or from north to south; but only from those observations made around the meridian and the nonagesimal. Otherwise, namely when the comet's orbit describes some circle nearly parallel to the equator or the ecliptic, and the comet stands too far from the meridian and the nonagesimal, then parallaxes are certainly in no way explored by this method. The former indeed always actually held for our comet: its orbit passed over both the equator and the ecliptic at a very wide angle. But as for the latter, very few observations around the meridian [Meridiem] and the nonagesimal came our way; hence also only very few parallaxes can be drawn out by this method.

The reason why parallaxes cannot be deduced from positions of the comet too far removed from the meridian and the nonagesimal is this: the angle of the vertical and the declination (as is evident from the figure), and likewise that of the vertical and the latitude, become larger the farther the comet is removed from the meridian or the nonagesimal; and the larger these angles are, the less accurately the parallaxes come out; and then they always turn out smaller than the proper ones. But the nearer the phenomenon is to the meridian and the nonagesimal, the more acute the angles become, so that at the meridian or the nonagesimal itself the said angles vanish entirely, and the vertical circle coincides completely with the circle of declination, as does the vertical circle with that of latitude; and then the difference of the true and the apparent declination is itself the true vertical parallax. The same is also to be understood of the latitudes near the nonagesimal.

Diagram. An engraved figure in a light plate-mark, standing at the right of the measure beside the paragraph above. A large circle, with a smaller circle at its upper left passing through E and B. A horizon line runs across it from M at the left to L at the right, lettered "Horizon." above it at the left. A straight line lettered "Æquator." (the equator) rises from O at the lower left to P at the upper right, and a curve lettered "Ecliptica." (the ecliptic) rises from N at the lower left towards the upper right. From A at the top, arcs descend to three points K on the horizon, and lines run from B towards the right. Three small circles on the arcs are lettered C; D and H stand on or beside the equator line below them. A further letter stands at the right of the uppermost C, at the end of a

short line drawn to the outer circle; its engraved form is not separated between Q and g. At the lower right stands the engraver's signature, "Aut. fculps." (the author engraved it).

- E (top of the small circle): E
- A (top of the large circle): A
- B (rim of the small circle, left): B
- C (three small circles on the arcs: upper right, middle, left): C, C, C
- Right of the uppermost C: [?] (Q or g; not separated)
- P (upper right, end of the equator line): P
- D (three, on or near the equator line): D, D, D
- H (three, on or beside the equator line): H, H, H
- K (three, on the horizon): K, K, K
- L (right end of the horizon): L
- M (left end of the horizon): M
- Horizon. (left, above the horizon line): the horizon
- Ecliptica. (along the curve): the ecliptic
- Æquator. (along the straight line): the equator
- O (lower left, start of the equator line): O
- N (lower left, start of the ecliptic): N
- Aut. fculps. (lower right): the author engraved it

But if no observations of comets are available so precisely around the meridian and the nonagesimal, you may indeed also bring somewhat more remote ones into the calculation and, by means of the angle of the vertical and the declination, reduce the fictitious parallax — that is, the difference of the apparent and the true declination — to the vertical one, provided the said angle is not too obtuse. I would have you note this well. Before we set out the calculation itself, however, I shall give two axioms, with whose help you can understand with almost no trouble whether any parallax is to be presumed from those observations.

Axioms of Parallaxes [Axiomata Parallaxium.]

1. If the declinations and latitudes are southern, the true ones are always smaller than the apparent ones; provided, that is, that some parallax inheres in the observations.

[Margin: Axiomata parallaxium.] *Axioms of parallaxes.*

2. But if the declinations and latitudes are northern, the true ones are always greater than the apparent ones, if some parallax underlies them; if there is none, you will find the contrary.

Let the parallax first be sought for December 23 at 7^{h} 22^{m} 7^{s} in the evening. At that time, from our table inserted on p. 129, there is found:

Apparent declination	17° 2′ 26″	*Bor.*
True declination	17° 21′ 26″	from our Ephem., Sect. XI, Book I, p. 129.
Differ.	19′ 0″	or the fictitious parall.

Since, therefore, the true declination is greater than the apparent, a parallax is certainly given. Let the angle of the vertical and the declination, *h c d*, therefore be sought, as we showed on p. 189 — although this time there is no need to investigate it, since it has already become known in the first investigation of the parallax, on p. 190. The whole calculation is therefore easily completed in the following way.

Mesol. of the fictitious parall.	19′ 0″	519812			
Antil. of the angle of the vertic. and declinat.	27° 3′ 29″	11591 *S.*			
Mesolog. of the vertical parall.		508221	21′ 20″	Vertical parall. at the altit.	44° 28′.

From the same observation, moreover, let us now also investigate the same parallax by the apparent and true latitudes, so that we may see how it agrees with the one found earlier from the declination. The operation is almost the same, except that here you use the angle of the vertical and the latitude. This angle we do not have at hand, nor do we care to investigate it trigonometrically just now, lest I seem excessive to you, reader. For it will be almost the same whether we take it from an artificial globe or from calculation: even if the said angle is one or two degrees larger or smaller, the parallax is still hardly changed by it, only by a very few seconds.

[Margin: Parallaxis ex declinatione.] *Parallax from the declination.*

1.

For December 23, then, at $7^h\ 22^m\ 7^s$ *vesp.*	Apparent latit.	3° 0′ 21″	*Austr.*	
	True latit.	2° 38′ 30″	*Austr.*	Since, therefore, it is smaller,
according to the preceding axiom 1, a parallax is therefore given		21′ 51″	ficti-tious	
Of this fictitious parallax	21′ 51″	Mesol. 505838		
Angle of the vertic. and latit.	12° 0′ 0″	Antil. 2209 *S.*		
		Mesol. 503629	22′ 20″	Parall. reduced to the vertical
at the altitude of the comet of about 44 deg.				

2.

For the 26th, at $6^h\ 0^m\ 0^s$, when the comet formed a straight line with the two in the foot of Perseus.

Apparent declination	31° 19′ 31″	*Bor.*		
True declination	31° 30′ 0″	*Bor.*		
Differ. of declin.	10′ 29″	Mesol. 579279		
Angle of the vertic. and declin.	40° 0′ 0″	Antil. 26651 *S.*		
		Mesol. 552628	13′ 41″	Parall. reduced to the vertical
at the altitude of the comet of about 50 deg.				

[Margin: Parallaxis pro die 26Decemb.] *Parallax for December 26.*

3.

For the 26th, at 11^{h} 44^{m} 48^{s}, the comet standing at an altitude of 51° 36′ 15″.

Apparent declination	32° 10′ 11″			
True	32° 16′ 56″			
Differ. of declinat.	6′ 45″	Mesol. 623303		
Angle of the vertic. and declin.	37° 0′ 0″	Antil. 50780 *S.*		
		Mesol. 572523	11′ 13″	Parall. reduced to the vertic.

511

And so you have, for December 23 and 26, the comet's parallaxes of altitude from the declinations and latitudes, agreeing very well indeed with the parall. found above. It would certainly be pleasing if we could elicit them in the same way for the following days; but because of the excessively obtuse angle, this is in no way possible.

Parallaxes of the Comet from the apparent and true declinations.

511 the page sets these calculations unruled, labels and figures in their own columns, and each is given here as one block, its rows in the order printed. The calculation for December 23 by the latitudes and the two for December 26 are numbered 1, 2 and 3 on the page. In the first of them the sentence "since, therefore, it is smaller … fictitious" is printed at the right of the true latitude and runs on below it, ending with its figure. The marks are printed after the apparent declinations of December 23 and of the second and third calculations, after the apparent latitude, after the fictitious parallax in its two Mesol. rows, after the 21 of the first result and the altitude beside it, after the reduced parallaxes, and after the figures in the captions; the rest are supplied in the house form. The page prints no mark after the 20 of the first result. No figure is supplied, and no degree figure stands before 19 0, 21 20, 21 51, 22 20, 10 29, 13 41, 6 45 or 11 13. The tags *Bor.*, *Austr.* and *S.* and the time tag *vesp.* are the page's own.

Com-putation	At what time the observations were made: Day, Month	Hour, Min., Sec.	Altitude of the comet (Deg., Min., Sec.)	Northern declinations of the comet (Deg., Min., Sec.)	Fictitious parallax (Min., Sec.)	Vertical parallax (Min., Sec.)	Horizontal parallax (Min., Sec.)
1.	December 23	$7^h\ 22^m$ *v.*	$44^\circ\ 28'\ 0''$	$17^\circ\ 2'\ 26''$ apparent $17^\circ\ 21'\ 26''$ true	$19'\ 0''$	$21'\ 20''$	$29'\ 54''$
2.	December 26	$6^h\ 0^m$ *v.*	$50^\circ\ 0'$ *circ.*	$31^\circ\ 19'\ 31''$ apparent $31^\circ\ 30'\ 0''$ true	$10'\ 29''$	$13'\ 41''$	$17'\ 52''$
3.	December 26	$11^h\ 44^m$ *v.*	$36'\ 15''$	$32^\circ\ 10'\ 11''$ apparent $32^\circ\ 16'\ 56''$ true	$6'\ 45''$	$11'\ 13''$	$18'\ 3''$

512

It now remains for us to examine the parallaxes also by the problem of the most ingenious Regiomontanus: a problem otherwise very well known to astronomers, celebrated by many, and also frequently applied to comets, for instance by Thaddaeus Haggetius [Tadeáš Hájek], Claramontius and others. To tell the truth, this is an invention that falls short in ease and certainty more than in subtlety and ingenuity. For this reason Tycho Brahe, Kepler and Crüger, men highly versed in this arena, also rejected the method outright, holding firmly that, even if that invention has acumen enough, it is nevertheless frustrated by the practice of calculation. Tycho discusses this matter splendidly and rightly in Book II on the Comet of the year 1577, p. 145: *Regiomontanus, in his second problem, where he makes each parallax in the circle of altitude known by two altitudes taken before or after the meridian in different azimuths, the time elapsed between those same two observations also being known, offers a subtle and quite ingenious speculation indeed, but one that in those smaller parallaxes, such as occur in the aether, deserves no place at all. For it builds the greatest things out of the smallest, so that an error of one or two minutes in the time, which can easily creep in, grows into an excessive deviation; and further, unless the azimuths and altitudes are obtained so scrupulously that nothing is wanting, you will have lost (as the saying goes) your oil and your labour. For a slip of a few scarcely perceptible minutes in the time and the other data easily brings about a departure of several degrees from the target of truth.* So he.

[512]a ruled, boxed table of eight columns under a caption. The head "Quo tempore fuerint observationes habitae" runs across the day column and the time column; the unit rows (Day, Month; H., M., Sec.; Deg., M., Sec.; M., Sec.) are the page's own, set in the house form in the cells. Each calculation takes two printed lines in the declination column, the apparent declination above and the true below, with the number, date, time, altitude and the three parallaxes standing between them; they are given here as two rows, with those cells in the first. The time tag *v.* and the tag *circ.* after the altitude of the second row are the page's own; that altitude carries no seconds figure. A round dot stands above the 0 of the first altitude. No figure is supplied.

[Margin: Regiomontani modus Parallaxes detegendi.] *Regiomontanus's method of detecting parallaxes.*

[Margin: Tychonis ſententia de methodo Regiomontani.] *Tycho's opinion of Regiomontanus's method.*

Nothing is truer than these words. For this method rests on the truest time between the two observations, noted most accurately, and also on altitudes and azimuths perfect in every respect (as will be said more fully shortly); and yet, for many weighty reasons, these can hardly ever be had as precisely as this business requires. It is therefore very easy to go wrong in this way. Indeed, if you have erred by only some seconds in those data, let alone by a whole first minute, you will, believe me, very easily depart from the truth by a whole degree: as could be shown more fully, if I had a mind to dwell somewhat longer on these matters and to spend a little more time on them. Nevertheless, so as not to leave this matter wholly untouched, note what the most celebrated Tycho says further on this matter in Book I on the New Star, p. 517: *If we make the second altitude* (namely that of Hájek's observation) *lower by even a single minute* (he says), *the new star* (of the year 1572) *will not only not deserve to hold a place in the highest aether, but will be pressed down somewhat below the Moon besides.*

[Margin: Autoris hâc de re ſententia.] *The author's opinion on this matter.*

[Margin: Regiomontani modus admodùm lubricus.] *Regiomontanus's method is very slippery.*

Tycho passes almost the same judgement, in Book II, p. 429, on Andreas Nolthius, otherwise an outstanding mathematician, who had elicited a parallax of 5 degrees and more for the comet (of the year 1577): *If even three first minutes, with a quarter, were lacking in the time presupposed by Nolthius, it would follow from the same altitudes and azimuths that the comet had been devoid of all parallax.* P. Crüger, once my teacher, who is always to be held in the best of memory, also fully subscribes to this opinion, in his *Uranodromus Cometicus*, p. 91. For he says: *if on p.* 44 (of the *Uranodromus*) *the time of the later observation had exceeded by only two seconds, I would have found no parallax at all. But now, since it falls short by so many seconds, the parallax grows to almost half a degree.*

[Margin: Cui ſententiæ etiam Crügerus ſubſcribit.] *Crüger also subscribes to this opinion.*

I have myself experienced this more than enough. For even if you go astray by only a very few seconds, whether in the altitude, or the azimuth, or the time, derived either from clocks or from the altitudes of the fixed stars, nevertheless, if you have worked according to Regiomontanus, no slight error can intrude, one that sets up a parallax of a whole degree where in fact there is none. Not to mention, finally, that if you neglect one or two seconds in the calculation itself, you will sometimes suffer a loss of up to half a degree. Indeed, even if you have observed both the seconds and the thirds as diligently as possible, you will still elicit nothing at all accurate from this method. The reason is that this problem abounds in excessively enormous triangles: at one time the sides of the triangles are 30, 40, 50, 60 or 70 degrees, while the angles amount to only

1, 2 or 3 seconds; at another the sides given are very small, and the angles in turn very obtuse, so that, as geometry teaches, nothing at all certain can be hoped for from it. For any error, however slight at first, mixes itself more and more with one absurd triangle after another, and grows more fruitful as the operation proceeds, so that in the end it produces a very notable error. Add, if you like, that you solve all the triangles in Regiomontanus's calculation by some definite geometrical method, from certain givens, as exactly as possible; yet if you assume other data again (angles, namely, in place of sides, or vice versa sides in place of angles) and use another way of solving the triangles, almost never does one and the same result come out. Hence, with one definite method of calculation correctly begun, the parallax runs at one time to about half a degree, and with another method of calculation, equally definite, at another time to scarcely a very few minutes, even though everything has been computed with equal diligence. We shall give a clear example of this in the second calculation that follows: in it the parallax came out at 25 minutes by Crüger's way, whereas, when my method is kept, although it rests on equally solid foundations, it is only 10′.

[Margin: Neglecto uno alterove ſecundo in calculo Regiomontani, ad ſemigradum aberrabis.] *If one or two seconds are neglected in Regiomontanus's calculation, you will go astray by up to half a degree.*

[Margin: Quare iſta methodo nihil certi acquiratur.] *Why nothing certain may be obtained by this method.*

[Margin: Evidens demõſtratio quod calculo Regiomontani nullâ ratione innitendum ſit.] *A clear demonstration that Regiomontanus's calculation is in no way to be relied on.*

Therefore, in whatever way you approach Regiomontanus's calculation, you will nonetheless always have something you may rightly doubt; nor will you ever be able to be sufficiently certain whether the parallax amounts to a few minutes or to a few degrees. The most sagacious Kepler strongly supports me in this, in the *Hyperaspistes*, p. 73, against Claramontius, when he says: *And so not only in the smallest parallaxes, as Tycho said, does this demonstration have no place, but not even in large ones, which Tycho was prepared to concede to Regiomontanus, is any security to be hoped for. In short, so great an agreement of the time interval with*

[Margin: Nunquam in calculo Regiomontani acquieſcere potes.] *You can never rest content with Regiomontanus's calculation.*

[Margin: Aſſentit Kepplerus.] *Kepler agrees.*

the azimuths cannot be hoped for from the observer's diligence that both can be mixed together at once in the same demonstration, and the one inferred from the other by reasoning, as the method of the demonstration requires, and compared with the nearest observations in order to establish the angles L Z N, L N Z. For the whole matter turns on the proportion of these triangles.

Since, therefore, this method of Regiomontanus is so doubtful and ambiguous that nothing whatever of the truth can be elicited by its help, it is rightly

asked here why, then, I have proposed to investigate the parallaxes by this method. I answer: although I am entirely of the opinion that nothing at all accurate and solid is extracted in that way, let alone that parallaxes more certain than ours, found by the distances, can be given by it, nevertheless, lest anyone persuade himself that I have understood the analysis of this calculation not in the least correctly, or have avoided this calculation on purpose, I wished to examine the parallaxes by means of this one too. In this way it may at the same time be clear to everyone that the parallaxes to be found by this method also differ little or not at all from those found above, so that we may thus be the more secure that the parallaxes have been deduced most exactly, since almost all of them, each and every one, agree in every respect, by whatever route they have been investigated. But if this problem produced quite peculiar parallaxes, far different from the earlier ones, whether large, or very small, or even none at all, while all the other investigations, that is, clearly maintained the contrary, I would attribute nothing whatever to it.

[Margin: Cur Autor nihilominus hâc viâ parallaxes iverit quæſitum.] *Why the author nevertheless went to seek the parallaxes by this route.*

[Margin: Etiam parallaxes Regiomontani methodo erutæ noſtris optimè reſpondent.] *Parallaxes extracted by Regiomontanus's method also agree very well with ours.*

Indeed, Regiomontanus's calculation not rarely shows no parallax at all, when in fact there is some; at times it shows a parallax of only a very few seconds, when in fact the parallax amounts to many minutes; at times, too, the contrary happens, as will be made very plain from the first example below, to be set up for December 27. For there, at an altitude of the phenomenon of 52° 24′, the parallax of altitude is given as only 33″ and the horizontal as only 54″; whereas countless other investigations, worked out in very different ways and with the greatest diligence, for the same day, the 27th, and the same altitude, all show that the parallax was 11′, 12′, or even 14′. Again, from the second calculation the parallax is found to be 25′, although all the other inquiries consistently indicate a parallax of scarcely 5 or 6 minutes.

[Margin: Abſurditates calculi Regiomontani.] *Absurdities of Regiomontanus's calculation.*

But so that you may see that the matter stands entirely as we have just said, I wished, and not grudgingly, to investigate the parallaxes by four different calculations, and indeed by means of logarithms, which, so far as I know, has not been undertaken before now. We shall therefore append the whole calculation: partly so that beginners may better grasp the entire process of this computation, which, by reason of the very many triangles to be solved, is otherwise very intricate and lengthy; partly so that the more skilled may more easily examine each member of this calculation, and see without any labour that everything has been deduced duly and rightly.

First, therefore, it will be necessary for us to explain in order and clearly, with the help of two diagrams, the whole analysis of the calculation to be set

up. On this occasion I want you to know at the same time that Regiomontanus founded this problem on two altitudes and azimuths observed at a fixed time, and presupposed that the comet was entirely free of proper motion. But since our comet continually exercised a notable proper motion, this problem not so barely, as indeed

[Margin: Quâ cautelâ hîc calculus incipiendus eſt.] *With what caution the calculation is to be begun here.*

proposed by the author, is to be begun; rather, it first needs a limitation, namely of the distance from the meridian, and then of the altitude and azimuth of the second observation. How this should be done, and above all by what method the proper motion may be wholly removed and the azimuths reduced, so that the comet stands as if motionless and endowed with no motion other than that of the primum mobile, Tycho Brahe has explained very suitably; and we shall follow him on this occasion too.

In the first of the diagrams set here, let H A N be the meridian, H N the horizon, K M the equator, A the vertical point, B the pole, the circles A G and A F circles of altitude, B I and B E circles of declination, and P C D O the orbit of the comet, so that the comet, by its proper motion between the earlier and the later observation, has advanced from C to D. Since, then, our comet, tending upward, made the later altitude in the second observation greater by its proper motion (namely because its declination was increasing) than if it had been wholly free of all proper motion and its declination had always remained the same in both observations, it will therefore have to be investigated at the outset how great, namely, or how much smaller, both the altitude and the azimuth of the comet in the later observation would be, the comet being supposed entirely free of all proper motion. When these have been found, we first take up that problem of Regiomontanus.

[Margin: Proceſſus calculi Regiomontani.] *The procedure of Regiomontanus's calculation.*

Diagram. An engraved block standing across the text measure between the two paragraphs, printed upside down, so that every label stands inverted to the text; it is described here turned upright. Two circles stand side by side, each a sphere projected in a circle with its horizon, arcs and dotted construction lines, and the comet's points marked; no caption is printed. The words are engraved script, the point letters roman capitals.

Left circle in the upright view (the right-hand circle as the page stands): the outer circle; a curve across the middle from N at the left rim to H at the right rim, labelled "Horizon." above it at the left; a straight line from L at the lower left rim rising through the horizon to K at the upper right rim, with the word for the equator written along it at the lower left; arcs from B to I and to E on that line; arcs from A down to G and F on the horizon; a dotted line from O down through D and C to P beside E; a dotted line from A down to M; "Oriens." in the lower half.

- O (top of the rim, left of A)

- A (top of the rim)
- B (upper left rim)
- M (inside, foot of the dotted line from A)
- D (inside, on the dotted line)
- K (upper right rim, end of the straight line)
- C (inside, on the dotted line)
- I (on the straight line, right)
- P (beside E, end of the dotted line)
- E (on the straight line, beside P)
- N (left rim, end of the horizon)
- Horizon. (above the horizon, left): "Horizon"
- H (right rim, end of the horizon)
- G (foot of an arc on the horizon)
- F (foot of an arc on the horizon)
- the word along the straight line, lower left: "equator", its script initial not separated between A and Æ [?]
- L (lower left rim, end of the straight line)
- Oriens. (lower half): "East"

Right circle in the upright view (the left-hand circle as the page stands): the outer circle; a curve across the middle from C at the left rim to B at the right rim, labelled "Horizon." above it at the left; two parallel straight lines rising from D and from S on the lower left rim toward the upper right, carrying the two labels on the semid. arcs; H on the upper left rim and Z at the top of the rim, with arcs drawn from each; dotted lines from H and from Z to V outside the rim, and a dotted line from V down to T; L, I, M, X, N, Y, G and O at intersections inside; P and R at the feet of arcs on the horizon, and E and K below the horizon; "Oriens." in the lower half; below the circle at its right, the engraver's line.

- V (outside the rim, at the top)
- Z (top of the rim; a Z with a crossbar)
- H (upper left rim)
- T (inside, end of the dotted line from V)
- A (upper right rim)
- L (inside, upper right)
- E (right rim)
- I (inside, beside L)
- M (inside, beside I)
- X (inside, left of I)
- Y (inside, right of N)
- G (inside, on the upper straight line)
- N (inside, below I)
- Horizon. (above the horizon, left): "Horizon"
- Arcus ſemid. Com. verus (along the upper straight line): "the comet's true semid. arc", the abbreviation semid. left unexpanded

- O (inside, on the horizon's upper side)
- C (left rim, end of the horizon)
- B (right rim, end of the horizon)
- P (foot of an arc on the horizon)
- R (foot of an arc on the horizon)
- Arcus ſemid. Com. viſus. (along the lower straight line): "the comet's apparent semid. arc"
- E (below the horizon, beside K)
- K (below the horizon, foot of the arc from O)
- D (lower left rim, end of the upper straight line)
- S (lower left rim, end of the lower straight line)
- Oriens. (lower half): "East"
- Autor ſculpſit. (below the circle, right): "The author engraved it."

All printed labels are listed; none was left unread. Which straight line ends at A and which at E on the right rim of the right circle was not traced.

Thus: 1. Let the angle A B C of the later observation be sought; it becomes known from the sum (in this our first example) of the comet's ascensional difference in each observation and of the distance from the meridian.

2. In the triangle A B C, given the angle A B C that has been found, and A B, the complement of the elevation of the pole, let the perpendicular A M be explored. Likewise B M, from A B and the perpendicular A M.
3. When B M is subtracted from the complement of the declination of the earlier observation, M C will remain.
4. From M C and A M let A C be investigated; its complement to 90° is the limited altitude of the comet in the second observation, as if it had lacked proper motion.

With this corrected altitude found in this way, let the corrected azimuth of the second observation also be computed.

1. In the triangle B A M, from A B, the complement of the elevation of the pole, and M B, found above, let the angle M A B be sought.
2. In the triangle C A M, from A C, the complement of the limited altitude, and C M, likewise found above, let the angle C A M be investigated.[513]
3. Let the sum C A B of these two angles be subtracted from the semicircle, and you will have the angle H A F, or H F, the limited azimuth of the second observation, as if it had had no proper motion.

With the altitude and azimuth of the later observation thus corrected, let us elucidate Regiomontanus's diagram itself, so that we may proceed more successfully with the task we have undertaken.

[Margin: Dilucidatio Schematis Regiomontani.] *Elucidation of Regiomontanus's diagram.*

In the second of the two figures attached, let B S be the horizon, B Z S the meridian, Z the pole of the horizon, H the pole of the equator, A L G D the

[513] in steps 1 and 2 the two givens of each triangle are printed one above the other between tall square brackets, with "ex" before them and the instruction for the angle sought after them.

true semidiurnal arc, and Q O S the apparent one. O is the apparent place of the comet in the earlier observation, G its true place; M is the apparent place of the comet in the later observation, L its true place; and O K is the apparent altitude of the earlier observation, G K the true one. Likewise R M is the apparent altitude of the earlier observation, R L the true one; L G is the true arc of time [arcus temporarius] between the two observations. To its endpoints L and G let the circles of declination H L and H G be drawn; let L H N be made equal to the angle G H O, and through N let a third vertical circle, Z N P, be drawn.

Since, then, the comet entirely lacks proper motion (as indeed it has actually been stripped of all proper motion by the preceding calculation), it therefore advances from the true place G to the true place L; and with the same quantity of motion it also advances from the apparent place O, along the apparent semidiurnal arc, to the point N. Once L N is drawn, therefore, it is equal to G O, just as N H is equal to O H, and the angle L H N to the angle G H O; hence the triangles L H N and G H O are entirely equal to each other, so that, for the calculation, the one may rightly be used in place of the other. From this it is proved that G O, or L N, is the parallax of the earlier observation, and L M the parallax of the later observation; these are what must be investigated on this occasion.

1. In the triangle Z H O, with the perpendicular H V let fall, let the perpendicular H V be sought from Z H, the complement of the elevation of the pole, and V Z H, the complement of the azimuth of the earlier observation. Then in the right-angled triangle H V O, from the perpendicular H V and H O, the complement of the declination of the earlier observation, let V O H, or Z O H, or G O H be explored. Or, what is the same thing, let a perpendicular be let fall from Z onto the line O H; then from the angle O H Z, the distance from the meridian of the earlier observation, and H Z, the complement of the elevation of the pole, let the perpendicular be sought; finally, from this perpendicular and O Z, the complement of the earlier altitude, the angle Z O H is found.

[Margin: Methodus Calculi.] *Method of the calculation.*

2. Since the angles G H O and L H N are entirely equal to each other, if you add the common angle N H G to each, the angle L H G will also be equal to the angle N H O, because the arcs L G and N O, described from the same pole, are similar to each other. Therefore, when G L or O N, or the angle L H G, the interval of time converted into degrees and minutes, is subtracted from the angle Z H O, namely the distance from the meridian of the earlier observation, the angle Z H N will remain: the distance from the meridian in the later observation.
3. In the triangle Z H N, with the perpendicular Z T let fall, the perpendicular Z T is found from the side Z N, namely the complement of the elevation of the pole, and the angle Z H N just found. From this perpendicular Z T and Z H, let the side H T be computed; it is to be subtracted from the complement of the declination of the earlier observation, so that

N T remains. Then, by means of this N T and the perpendicular Z T, let the required Z N be investigated. If it is greater than Z M, namely the complement of the limited altitude (which in the preceding figure of Tycho's limitation was called A C), some parallax lies hidden in these observations; but if Z N is equal to Z M, or somewhat smaller, there is no parallax present at all, and so the calculation ends here; but if it is greater, it is to be continued.

[Margin: Ex quibus cognoſcatur parallaxin ſubeſſe.] *From which it may be recognized that a parallax is present.*

4. In the right-angled triangle Z T H, from the hypotenuse Z H, the complement of the elevation of the pole, and H T, found in step 3, let the angle T Z H be explored; then in the triangle Z T N, from N Z, found above, and N T, let the angle N Z T be sought. Let the sum of this angle and the angle T Z H be subtracted from the semicircle, and you will have the angle B Z P; when it is taken from B Z R, the corrected and limited azimuth of the second observation, the angle R Z P, or L Z N, will result.
5. In the orthogonal triangle Z T N, the angle Z N T, or Z N H, is found from N Z and T Z.
6. In the oblique-angled triangle M Z N, let the perpendicular M X be sought from Z M, the complement of the apparent limited altitude of the second observation, and the angle R S P, found in step 4; again, from this perpendicular M X, now found, and Z M, the side Z X; let it be subtracted from Z N, found in step 3, and the remainder is X N. Afterwards, from X N and M X, M N will result.
7. In the right-angled triangle Z M X, from Z M and Z X let the angle Z M N be computed; likewise, in the smaller triangle M X N, also right-angled, from M N and N X, the angle N M X. The sum of these two angles, once found, gives the angle Z M N, or L M N.
8. In that smaller triangle M X N, let the angle M N X, or M N Z, also be investigated from M N and M X.
9. To this angle M N Z that has been found, let Z N H, obtained in step 5, be added, and you will have the angle M N H; when the angle L N H, found in step 1, is taken from it, the angle M N L, or M N I, will remain.
10. Finally, in that small oblique-angled parallactic triangle M N L: since L N is equal to G O, once this side is known, the parallax of the earlier observation itself becomes known; and once L M has been found, the parallax of the later observation itself. Before one arrives there, however, let the perpendicular M I be let fall from the obtuse angle N M L; it is to be sought from M N, found in step 6, and the angle M N L, or M N I, obtained in step 9.

[Margin: Prodit Parallaxis.] *The parallax emerges.*

11. In the right triangle M I N, let N I be computed from M N and the perpendicular M I.

12. In the same triangle, from M N and N I, the angle N M I is found; subtracted from the obtuse angle N M L, obtained in step 7, it leaves the angle I M L.
13. Finally, in the triangle M I L, from the side M I and the angle I M L just found, I L becomes known; when N I (step 11) is added to it, L N will result: the parallax of the earlier observation, namely of the smaller altitude.
14. Lastly, from the perpendicular M I (step 10) and I L (obtained in the preceding step), L M is found: the parallax of the later observation, namely of the greater altitude.

This, then, is Regiomontanus's method of calculation. It is not only quite lengthy, tedious and intricate, but also depends on resolving many triangles, and ill-formed ones at that, so that hardly anything certain can be drawn from it at any time or from any observations whatever. Moreover, if we examine the matter more deeply, the source of error lies hidden not only in the first steps of the calculation (namely, that the bare altitude and azimuth mostly differ from the limited ones by only a very few seconds, so that the angle L Z N mostly amounts to only a few seconds); above all, some doubt also arises in the later part of the calculation. From such very small sides as M N and N X, namely, an angle can in no way be explored accurately: for instance, in step 7, the angle N M X; in step 8, the angle M N Z or M N X; likewise in step 12, the angles M N I and I M L, and so on. For if you depart in the sides by even one or two seconds only (as can easily happen), you will certainly be mistaken in the angles by several degrees. Therefore, if the angle M N I is changed by only one degree, or at most two, then instead of a parallax of a few minutes you will surely have another of several degrees. So much so that, as we have often impressed before, there is no certainty at all in this calculation, since those monstrous triangles in the earlier part of the calculation cannot by any means be eliminated. In the later steps of the calculation the task is indeed helped to some extent if you assume entirely different triangles and more suitable givens; but this does not satisfy completely. Meanwhile, however, I shall briefly set out here this method of carrying out the calculation as well, which I have devised: both so that the investigation itself, from step 4 to 13, may become somewhat easier and the triangles may be constructed far more expeditiously, and above all so that the angle I M L, which is obtuse and mostly fills out a right angle, may be avoided entirely.

[Margin: Regiomontani calculus benè prolixus & tædioſus eſt.] *Regiomontanus's calculation is quite lengthy and tedious.*

[Margin: Quo in calculi membro error potiſſimus lateat.] *In which step of the calculation the chief error lies hidden.*

[Margin: Monſtroſa triangula hâc ſervatâ methodo neutiquam evitari poſſunt.] *While this method is kept, the monstrous triangles can by no means be avoided.*

[Margin: Quâ ratione ex parte huic calculo ſubveniri poſſit ?] *By what means this calculation can be partly helped?*

First: once step 8 is done, let the perpendicular N Y be let fall from the point N onto the vertical circle Z R; it is to be sought from Z N (obtained in step 3) and the angle N Z L (known from step 4). Then, in the same triangle Z Y N, let the angle Y N Z be explored from the perpendicular Y N and the earlier angle N Z L; likewise the side Y Z, given the two sides N Z and Y N.

Second: from the angle M N Z, obtained in step 8, subtract the angle M N L; the remainder gives the angle L N Z. Let this in turn be subtracted from the angle Y N Z, found in the preceding step, and you will have the angle Y N L.

Third: in the triangle Y N L, from the side Y N and the angle just explored, let the side Y L be sought; it is to be subtracted from Y Z (computed in step 1), and Z M will remain. Let this in turn be taken from M Z, that is, from the limited altitude found at the outset, and thus L M, the parallax of the later observation, will result.

Fourth and last: in the triangle L Y N, from the two sides L Y and Y N, let the hypotenuse L N be sought: the parallax of the earlier observation.

Just as I much prefer this method of calculation to the other, so for the most part it also agrees better with those parallaxes investigated through distances. And yet this aid does not make the whole calculation of Regiomontanus, as we have indicated, altogether more complete and more certain, so that we could rely on it alone. But insofar as it corresponds very closely with the other investigations of parallaxes carried out through distances, to that extent it is to be tolerated; but if the calculation of Regiomontanus alone indicates the contrary, it is to be rejected entirely.

[Margin: Quâ ratione calculus Regiomontani tollerandus ſit ?] *In what way Regiomontanus's calculation is to be tolerated?*

Since, therefore, we have already examined the parallaxes by safer and various routes, now these too by this route of Regiomontanus, and indeed, in this first example, according to the former method, from two altitudes and azimuths observed on the evening of 27 Dec.

[Margin: Diverſitas adſpectus exploratur juxta Regiomontanum.] *The parallax is explored according to Regiomontanus.*

[Margin: Vnde conſtet parallaxin obſervationibus ſubeſſe.] *From which it may be established that a parallax is present in the observations.*

Since, therefore, Z N is 7″ greater than the complement (namely, of the limited altitude) Z M, it follows that some parallax is present in the observations, and the calculation must be continued. But if they had been equal, or Z N somewhat smaller, then no parallax at all could have been expected.

520

[Margin: Ex hâc inveſtigatione parallaxis nimis exilis prodit.] *From this investigation the parallax comes out far too slight.*

Thus, by this method of Regiomontanus that we have taken up, the parallax for 27 December at 5^h in the evening, at an altitude of the comet of about 53°, comes out as only 33″ or 52″; and consequently the horizontal parallax as 55″, or at most 1′ 26″. Above, however, from the distances and altitudes, that same parallax came out larger: 10, indeed 12, minutes. But so that the matter may become more certain, let us explore, by yet another inquiry for this same 27 December but from two different observations, whether such a slight parallax springs out again. We will set up the calculation first by the usual method, and then also by that other method which we gave above.

Investigation of Parallax II, for 27 December [Inveſtigatio Parall. II. ad diem 27 Decembr.]

1 Obs. at	$5^h\ 23^m\ 58^s$	Altit. of the com.	51° 16′	Azim. 78° 55′	*Or. M.*	Declin. of the com.	34° 33′ 14″

[Margin: Nunc rursùs nimis magna reperitur parallaxis.] *Now, in turn, the parallax is found far too large.*

[524]set unruled, in the page's own columns, with short rules under several figures. The marks are printed after 35 1 37 (twice), 42 17 0, 35 1 1 (three times), 90 0 0, 53 (twice), 0 53, 0 36 (twice), 0 35 and 23 52 (twice), and over 0 0 36 in step 14; where the marks stand alone over the arc of the next line, they are set in a cell of their own. The rest are supplied in the house form; no figure is supplied. The 0 of 0° 0′ 36″, 0′ 53″, 0′ 38½″, 0′ 36″ and 0′ 35″ is printed. In step 6 the three givens are gathered between curly braces, "6. In triang. M Z N ex" at the left and "quæratur latus M N." at the right. The step figures 11, 12 and 13 are set within the lines, as on the page. The signs + after the logarithm and mesologarithm in step 14 and the dash after the mesologarithm 366999 are the page's own, as are the tags *A.*, *S.*, *Add.* and *Ad.* and the point-letters. As printed: the arc of T Z is set as 22° 42′ 45″; the angle M N H as 86° 47′ 6″, where 46° 20′ 6″ and 42° 17′ 0″ make 88° 37′ 6″; the logarithm of the perpendicular M I as 864026, where 826662 and 38364 make 865026; the antilogarithm of M N in step 11 as 0.00300, against 0.00331 in step 6; and the logarithm of the angle N M I as 14495, where 868157 less 826662 is 41495.

Just as the parallax came out almost too slight from the earlier calculation, so from this one, just completed, it shows itself far too large. From this it is plain that very little trust is to be placed in these calculations. For when the angles are too obtuse and the sides, in turn, are given very small, nothing certain can be drawn out. And to show more clearly that the method of this calculation is very unsteady, we will attempt the same task by resolving entirely different triangles, and with other data; and so you will find that in this way the parallax, hitherto almost twice as large, can be made smaller than the one found earlier from the same observations: this however, could by no means happen if this problem of Regiomontanus rested on solid foundations, that is, if it enjoyed well-proportioned triangles.

[Margin: Aliâ viâ demonſtratur calculum Regiomont.vacillare.] *By another route it is shown that Regiomontanus's calculation is unsteady.*

525

[Margin: Methodo Regiomontani ad diem 31 Dec. & 1 Januarii parallaxes inquiruntur.] *By the method of Regiomontanus the parallaxes for 31 Dec. and 1 January are investigated.*

From this, then, it can be seen that if you proceed by this route, which is equally well founded in geometry, the parallax comes out smaller by a quarter of one degree than the one that was derived by Crüger's route; so it is easy to go astray in this calculation, as we have already shown at sufficient length above. Nevertheless, if one ever wishes to investigate parallaxes following Regiomontanus, it is better to proceed by this latter method that I have handed down.

Although we attribute little to this calculation (however closely it agrees with our earlier ones, and indeed shows a parallax almost smaller still than the earlier, more solid investigations), let us nevertheless add one or two more examples of the same kind, so that by this reasoning too it may become clear how great the parallaxes come out, both for 31 December and for 1 January: larger than those found, or in fact smaller? For lack of observations, however, we shall have to use altitudes subject to refraction, so the refraction must be carefully attended to. Here it should also be noted that the following observations, from which the calculation is to be set up, were made in the western quarter, just as those of the preceding operations were made in the eastern quarter. Hence other, inverted diagrams would indeed be needed as well; but since each calculation arrives at an absurdity, so that it cannot be carried through to the end, we shall rest content with those two preceding figures.

525 set unruled, in the page's own columns, with short rules under several figures. The marks are printed after 35 1 37 at its three places, 0 38 in step 1, 46 30 6, 4 40 in the line of step 3, 0 0 38, 0 10 9, 10 9 and 10 10; where the marks ° ′ ″ stand alone over the arc of the next line, they are set in a cell of their own. The rest are supplied in the house form; no figure is supplied. The 0 of 0° 1′ 7″, 0′ 38″ and 0° 0′ 38″ is printed; 9′ 33″ is printed without a degree figure. The sign + after the logarithm and the mesologarithm, and the dash after the mesologarithm of the angle, are the page's own, as are the tags *A.*, *S.*, *Subt.* and *Add.* and the point-letters. As printed: the line of step 3 gives Y N as 4′ 40″, where the calculation uses 0′ 38″; and the logarithm of Y N at 0′ 38″ stands 858641 in step 1 and 859141 in step 3.

[Margin: Cur in hoc exemplo nulla detur diverſitas adſpectus.] *Why no parallax occurs in this example.*

Since, however, Z N is less by 55″ than Z M, the complement, that is, of the limited altitude, there is therefore no parallax at all here. For that parallactic triangle L M N vanishes entirely, namely when Z N is less than Z M; and then the comet is, as it were, raised in the opposite direction, since, namely, the observations were made in the west. But if they had been made in the east, there would certainly have been a parallax. You see, then, how accurately this investigation agrees with the earlier ones, although above, for the same day, the 31st, a parallax that was still perceptible was detected.

[Margin: Parallaxis penitùsevaneſcit.] *The parallax vanishes completely.*

Since, therefore, Z N is again less by 16″ than Z M, the complement, that is, of the limited altitude, hence the parallax also vanishes entirely here (just as all the earlier, most accurate inquiries also clearly demonstrate); for Z N ought to be greater. For the comet stood in the western quadrant, and in descent. But when the comet is in the eastern quadrant and in ascent, as in the two earlier examples, then Z N always turns out greater than Z M, if some parallax lies hidden.

[Margin: Ritè nunc deductis parallaxibus demonſtrativè probatur quo loco hoc vel illo die Cometa hæſerit.] *Now that the parallaxes have been properly derived, it is proved demonstratively in what place the comet stood on this or that day.*

Let us now at last put an end to these labours of investigating the parallaxes, since, more than enough (I think), from 23 December up to 1 and 4 January,

[529] the calculation is set unruled, in the page's own columns, with short rules under several figures. The marks are printed after the interval 18 0 (as ′ and ″), after 4 30 0, after the 51 of the remark on the angle, and after 35 37 8; where the marks ° ′ ″ stand alone over the arc of the next line, they are set in a cell of their own. The rest are supplied in the house form; no figure is supplied. "Otherwise *Subt.*" stands at the right under "is added here", opened by a printed square bracket. The givens of step 3 stand between tall square brackets, with "Z N is sought" at the right. The tags *A.*, *S.*, *Add.* and *Subt.* and the point-letters are the page's own. As printed: the angle Z H N is said to be only 51″ greater than the angle found above (60° 59′ 10″ on the facing page), where the difference is 50″; and the interval G L is tagged "is added here", where 61° 0′ 0″ is 65° 30′ 0″ less 4° 30′ 0″.

we have examined the parallaxes in the most varied ways, and indeed with every diligence applied, so that a table of parallaxes could be constructed as well as possible for each degree of altitude and for each day of the apparition, and by means of them the true distance of the comet from the Earth could also be ascertained at any time whatever. Once these are known, it will be permissible not only to affirm with probability that the comet stood above the Moon, as was said in Books II and III, but it will also be proved demonstratively hereafter in what place the comet actually stood on this or that day and hour. This is surely the chief thing, which ought to be investigated by all writers on comets and seriously pursued: for the whole dispute among philosophers about the place of comets, aired until now, can be settled completely by that demonstration.

[Margin: Cur Autori haud concesſum fuerit parallaxes diverſorum horizontum explorare?] *Why was it not granted to the author to explore the parallaxes of different horizons?*

[Margin: Quomodo cum aliorum obſervatorum animadverſionibus comparatum fuerit.] *How matters stood with the notes of other observers.*

As for what seems to remain, I would indeed wish, and nothing would truly be more pleasing to me, that I could likewise derive parallaxes from the observations of other astronomers made here and there, and in this way investigate the parallaxes of different horizons with equal diligence and good faith. But however much I desire this, and though I would gladly apply every effort, I would nevertheless undertake this labour in vain at present. For no observations at all, sufficient and accurate enough, have come to hand by whose help this task could have been accomplished. Many observations were indeed made by most distinguished and most practised men in Italy, France and Germany; but with all those observations the case is such (which, however, I wish to be said with their leave) that I consider we can deduce nothing at all accurate from them: one presented observations only in a rough-and-ready way, scarcely indicating the comet's place by reference to a globe; another noted the time of the observation crudely; another, perhaps noting the time precisely enough, observed the comet's place, however, neither by distances nor by altitudes and azimuths; most judged the longitudes and latitudes of the phenomenon with the naked eye, only by stretched threads, that is, from estimated distances: but from all of these, believe me, nothing solid is gained. Indeed, even if one or another suitable observation is available (very few of which, however, are found), another to be joined with it is lacking in turn. For from a single one alone, as is well known, parallaxes can in no way be derived.

[Margin: Plurimæ accuratiſſimæ obſervationes ad calculum requiruntur.] *Very many, most accurate observations are required for the calculation.*

The best and surest observations of all were indeed made elsewhere, for 26 December, when all the diligent investigators of celestial things everywhere, in Germany, France, Italy, Poland, Hungary, etc., and indeed in Asia and Africa, caught the comet in the evening in one and the same straight line with those

two little stars in the foot of Perseus. Yet the smallest part of them observed neither the time exactly enough nor that straight line carefully enough; hence, too, the parallaxes are ascertained only approximately, and that the comet probably, at least, stood above the Moon. But since in Book III the parallaxes of different horizons were drawn from those same observations amply enough, as far as was allowed, and it is not permitted to go further, we must stop here.

[Margin: Quantæ extiterint genuinæ parallaxes Cometæ horizontales?] *How large were the comet's genuine horizontal parallaxes?*

To those who examine, however, and to the fair-minded who weigh, all and each of the horizontal parallaxes found so far for any days whatever of the whole apparition, it is clearly evident that the horizontal parallax on 23 December was not above 30′; on the 26th, not above 18′; on the 27th it did not reach 13′; on the 28th, scarcely 8′ or 9′; on the 30th, scarcely 4′; on 1 January, scarcely 2′; and on 4 January, scarcely 50″; and so on accordingly. Although, if the matter is weighed still more strictly, the parallaxes in the last days of the comet's apparition were still somewhat smaller; indeed, on 1 and 4 January they almost vanished: for the greatest of all that came out at that time was only 16″.

[Margin: Conceditur parallaxin die 4 Januar. extitisſe 52 ſecund.] *It is granted that the parallax on 4 January was 52″.*

Although these results are too certain ever to be denied, let us nevertheless be a little more generous and, as a favour to the Aristotelian sect, grant a somewhat larger parallax about the last days of the apparition: namely, that on the fourth day of January the horizontal parallax was 52″. On this proportion we have also constructed the following table of parallax, namely for every second degree of altitude on each day of the apparition. But what proportion is wholly inherent in these parallaxes we shall refrain from saying in this place, deferring it to where we have proposed to treat of the genuine distance and true place of the comet with respect to its elongation from the Earth, or where we have proposed to treat of the degrees and increments of the comet's velocity.

[Margin: Diſpoſitio Tabulæ parallaxeos.] *Arrangement of the table of parallax.*

The arrangement of this table, moreover, is as follows: the upper border shows the days, the lower the comet's distances from the Earth, in semidiameters and the miles attached to them; while the left-hand column shows the degrees of altitude, and all the rest the comet's vertical parallaxes themselves.

530a boxed, ruled table filling the page, under its caption, which stands inside the box. The head of each day column carries, on separate lines, the day, then "S.T.", the distance of the comet from the Earth in semidiameters, then the miles added to it, then the unit line; they are given here as the first five rows. In the label column "Year 1652" stands against the day heads, and the label "Deg. of apparent altit." is printed on three lines beside the distance rows; the label cell of the unit row is empty. The body runs from "Horiz." through the apparent altitudes 2 to 88 by twos, in groups of three separated by short rules; minutes and seconds stand as a pair in each day column and are set here in the house form; every 0 is printed. As printed: the day-27 head sets "S, T." with a comma, and the miles of 28 December are printed without a point after "Mil"; the figures at altitude 10 for 27 December carry a comma between the 1 and the 2 of the minutes, those at altitude 38 for 21 December a point after the minutes, and those at altitude 64 for 23 December a faint comma after the minutes. The caption's range runs to 12 January; the columns on this page end at 31 December, and the catchword announces a continuation overleaf.

531

[531] the continuation of the table on the previous page, for 1 to 12 January, set under the same caption, repeated, and in the same form: the day, then "S. T.", the distance of the comet from the Earth in semidiameters and the miles added to it, then the unit line, here given as the first five rows; the altitudes 2 to 88 by twos down the left-hand column, in groups of three separated by short rules. The label column gives the year as 1653. Every 0 is printed. The two pages are set here as two tables, as printed. As printed: the day-5 head sets a point before "Die".

Johannes Hevelius, Cometography, Book Five [JOHANNIS HEVELII COMETOGRAPHIÆ LIBER QUINTUS.]

On the True Place of the Comet and Its Distance from the Earth [De vero Cometæ loco,ejusq; à Terrâ diſtantiâ.]

[Margin: Arduum ſanè eſt negotium cujusvis Cometæ genuinum locum rectè explorare.] *It is indeed an arduous business to ascertain correctly the genuine place of any comet.*

Although correctly determining the true place of any comet is rightly counted among the foremost and indeed most arduous of all the matters that arise concerning comets, nevertheless, since in the preceding books a road has already been laid for us, at sufficient length, toward investigating this very business all the more accurately, and since, God also assenting, the genuine parallaxes of the comet of 1652 have now been duly established for any days of the apparition, it will not be so difficult for us to show in what part of the heavens our comet carried out its motion, and whether, in the course of time, it acquired always the same distance from the Earth, or rather a different one.

[Margin: An Cometa 1652 perpetuò eandem diſtantiam à terrâ conſervaverit?] *Did the comet of 1652 keep the same distance from the Earth throughout?*

In the Second and Third Books it has indeed already been shown with probability that this comet stood neither in the lowest nor in the highest region of the air, but hung, as an ethereal body, in the aether itself, far above the Moon. Now, however, we shall also prove by demonstration by how great an interval it was in fact removed from us.

[Margin: Cometa quotidie à nobis diſcesſit.] *The comet receded from us daily.*

To begin with, it must be understood that, just as the parallaxes diminished from day to day, in like manner the comet itself also became more remote every day, according to that axiom which is above all exception: the smaller the parallax, the more remote the phenomena. By means of this axiom the true seat and the distance of all ethereal bodies are demonstrated and established most exactly.

[Margin: Ordo Planetarum tam in Perigæo quàm Apogæo conſtitutorum.] *The order of the planets placed both at perigee and at apogee.*

Hence, with no one at all contradicting, it is most true that the Moon, on account of its very great horizontal parallax, is, according to each and every one of those skilled in astronomy, the nearest to the Earth of the remaining ethereal bodies, whether it is placed at perigee or at apogee. But with regard to perigee remoteness, once the horizontal parallaxes are properly considered (namely, according to those who acknowledge the Sun, and rightly, as the centre of the whole planetary system), the Moon is followed by Venus; then Mars, Mercury, the Sun, Jupiter, and finally Saturn, which is the most remote of all.

At apogee, however, matters stand very differently with the distances of the planets: for then the Sun itself is the nearest to the Moon, and after it in order follow Mercury, Venus, Mars, Jupiter, and so Saturn.

[Margin: Autores,circa Planetarum Parallaxes,nimiùm quantum inter ſe disſentiunt.] *Authors disagree among themselves exceedingly about the parallaxes of the planets.*

The astronomers, both ancient and more recent, do not, it is true, altogether agree among themselves about the horizontal parallaxes and the distances of the planets; rather, almost as many different opinions are found as there are authors who have written on this matter. And yet this diversity in no way impairs the order of the planets stated above; it only makes this or that planet now nearer, now more distant, as you will see sufficiently from the appended table. In it, following the foremost practitioners of astronomy, namely Ptolemy, Copernicus, Tycho, Kepler, Boulliau, Riccioli, and ourselves as well, you will have both the horizontal parallaxes of all the planets and their distances from the Earth, together, at greatest, mean and least remoteness. The opinions of the others, who seem to differ very little from these, are left aside, since the opinions of so many authors, as you will soon understand, suffice for the business they are to serve.

With the help of this table, too, we shall be able in due course to avoid a great many lengthy discussions, and to understand with almost no trouble how, namely, our comet stood in its parallaxes and distances from the Earth with respect to the planets.

Table showing the distances of the planets from the centre of the Earth, and their horizontal parallaxes, according to the various hypotheses of the astronomers [TABULA exhibens Diſtantias Planetarum à Centro Terræ, eorundemq́; Parallaxes Horizontales, juxta diverſas Aſtronomorum Hypotheſes.]

532

[532] The planet names stand in a narrow left-hand column, each printed sideways beside its group of seven rows; they are set here in the first row of each group. Distances are in semidiameters of the Earth (*Semid.* with the Earth sign); the parallaxes are in minutes, seconds and thirds of arc. The Moon's fractions are printed as a numerator over a denominator, without a bar.

[Margin: Quemadmodum Cometæ Parallaxes paullatim decreverunt, ſic phænomenum iſtud ſenſim altiùs evaſit.] *As the comet's parallaxes gradually decreased, so this phenomenon gradually rose higher.*

Since, therefore, at the end of the preceding Book IV the table itself of the parallaxes of the comet of the year 1652 has now been presented by us — the parallaxes both horizontal and at every second degree of altitude, duly and accurately computed, and indeed for each and every day of the apparition, namely from 20 December to 12 January — it is plainly evident to us that the parallaxes decreased successively. From this it is rightly concluded that the comet, receding perpetually from the Earth, became higher every day. Further, the table itself also shows how great an interval, on each day, the comet stood removed from the Earth, in semidiameters of the Earth. But so that everything may be set before the eyes still more clearly — namely, how the comet acquired a greater distance day by day — so that you may grasp the increments of its distances at once, as it were at a single glance, and so that it may the more easily be compared with the remaining comets with respect to its motion, I shall insert at this place a separate small table, showing only the horizontal parallaxes of our comet and its distances from the Earth, both in semidiameters of the Earth and in German miles.

[Margin: Parallaxes Cometæ 1652 horizontales,atq; diſtantiæ ejus à terrâ exhibentur.] *The horizontal parallaxes of the comet of 1652, and its distances from the Earth, are presented.*

The first column contains the days of the apparition, the second the horizontal parallaxes; the third and fourth show the interval from the Earth in semidiameters of the Earth and in German miles.

Table of the horizontal parallaxes and of the distances of the comet of the year 1652 and 1653 [Tabula Parall. horizontal. & diſtantiar. Cometæ anni 1652 & 1653.]

[Margin: Initiò Cometa Terræ fuit vicinisſimus.] *At the outset the comet was nearest to the Earth.*

It is therefore most certain that on 20 December, namely when it first met our eyes, the comet was nearest to the Earth, and was distant only 110 semidiameters of the Earth. Yet this distance of the comet, although it was the least at that time, was nonetheless evidently far greater than the Moon's. For the Moon, even when placed at apogee and in conjunction or opposition, is never more remote than 65 semidiameters of the Earth; and even supposing that you consider it at quadrature, nonetheless those who, like Riccioli and some other more recent astrosophers [Aſtroſophos], extend the system of the planets furthest, beyond all others, never place it higher than 66 semidiameters of the Earth.

[Margin: Cometa multùm remotior extitit Lunâ, etiam in minori ejus à terrâ diſtantiâ.] *The comet was much more remote than the Moon, even at its lesser distance from the Earth.*

Accordingly, with nothing whatever opposing it, nothing at all is truer than that the comet was much more remote than the Moon; indeed, that even in the place where it was least removed from the Earth it was found to be about twice as high. On 30 December, however, advancing, it reached the orb of Venus — that is, according to the opinion of Kepler, who (if you except Riccioli and ourselves) makes the planets most remote; and this Keplerian opinion, in this proportion, always, in favour of the Peripatetic school, we shall retain.

[Margin: Quâ die Cometa Solis regionem pervaſerit?] *On what day the comet reached the region of the Sun?*

On 1 January the comet reached the sphere of Mercury; by 4 January it had already passed beyond the Sun; by 5 January it had already passed beyond the orb of Mercury, by the 6th that of Venus, and by the 8th that of Mars; finally,

533 The rows stand in groups of three, ruled off from each other. The head "Distance from the Earth" spans the third and fourth columns. The parallaxes are in minutes and seconds of arc.

on 9 January it had reached the heaven of Jupiter, and by the 12th it had crossed almost the whole orb of Jupiter.

[Margin: Quâ dieCometa Jovis orbem attigerit.] *On what day the comet reached the orb of Jupiter.*

But if you prefer to follow our own view, which makes the planets more remote still by far, the comet was nonetheless already moving in the orb of Jupiter at that time, as you will clearly see from the two preceding tables.

[Margin: Quanto intervallo Cometa circa finem à terrâ remotus fuerit.] *How great an interval separated the comet from the Earth towards the end.*

No one, therefore, is so dull of mind as not to see easily that this phenomenon is an entirely ethereal body, since towards the end of its duration it stood removed from the Earth by 15,494 semidiameters of the Earth, that is, 13,324,840 German miles.

[Margin: Vnicum argumentum,pro ſede Cometarum à parallaxibus depromptum, abundè ſufficit, ad convellendas quasvis Peripateticorum opiniones.] *A single argument for the seat of comets, drawn from the parallaxes, is amply sufficient to overturn any opinions of the Peripatetics whatever.*

For this reason I consider it not at all worth the effort to go down into the arena with the Peripatetics themselves, examining and refuting their arguments — although, should the occasion arise, we shall perhaps not refuse to take this task upon ourselves as well. For this single demonstration from the parallaxes, astronomical and geometrical, here brought forward, is worth all the others. It suffices to refute all the opinions of our opponents, and also to establish that our comet dwelt in the highest aether: far indeed above the Moon, Mercury, Venus and the Sun, and even above Mars itself at apogee.

[Margin: Ad Saturnum uſq; Cometa evectus eſt.] *The comet was carried up as far as Saturn.*

Perhaps it was carried up even as far as Saturn. Yet since we did not see the comet any longer than 10 January, and obtained no further observations, we cannot affirm this with so much certainty. Even so, it is not so very contrary to reason that, had the Moon not hindered it with its light (for on that day its apparent diameter was still of notable size), the comet would without any doubt have been seen both for longer and far more remote still; for day by day it rose higher and higher, in a very notable proportion. Indeed, if you follow the proportion of the horizontal parallaxes properly, on 14 January, had the comet lasted until then, its parallax would necessarily have scarcely exceeded 5″, and so, as a consequence, it would have been higher than Saturn itself.

I am therefore quite certain that no one who weighs the matter well and rightly understands the nature of parallaxes will fail to grasp easily what place must be assigned to the comet.

[Margin: Autor minimè dubitat ſe Cl. Ricciolo plenè ſatisfecisſe, & more Mathematico abſolutè ſedem hujus Cometæ demonſtrasſe.] *The author does not doubt in the least that he has fully satisfied the distinguished Riccioli, and has demonstrated the seat of this comet absolutely, in the mathematical manner.*

I also do not doubt in the least that, by demonstrating absolutely the parallaxes of this comet and its distances from the Earth, I have fully satisfied the most learned Riccioli, and that he will therefore gladly concede that the seat of this phenomenon has now been demonstrated by us duly and accurately, and indeed mathematically. For he holds the view that no author whatever has so far demonstrated truly and absolutely, in the mathematical manner — however strenuously they have tried — but only probably, from a hypothesis, that comets stood either above or below the Moon. This is clear from the conclusion of Book VIII, Section I, pages 89, 96, 100 and 117, and above all from conclusions 2 and 3, where he says: *"No comet has yet been demonstrated by a mathematical demonstration to have been absolutely either above or below the Moon."*

[Margin: Quibus hæc nondum ſufficiunt, illi mantiſſæ loco ſibi habeant ea, quæ Rothmannus & Ricciolus de eâdem materiâ pronuntiarunt.] *Those for whom these things do not yet suffice may take, as a makeweight, what Rothmann and Riccioli have pronounced on the same matter.*

But if some of the Peripatetic tribe should still not rest content with these things, and, the parallaxes notwithstanding, should nonetheless defend tooth and nail that the comet was below the Moon and in the region of the air, I have (believe me) absolutely no wish on this occasion to dispute this matter with them at greater length. For since, against those who deny the principles, who scorn sound reasons and persist obstinately in their opinions, what is already done

I would be doing; I would waste my time and gain nothing at all. It is therefore better to send these people away, so that in future they may keep their own affairs to themselves. Meanwhile, however, by way of a finishing flourish, I shall add only the following, which I urge them again and again to weigh well among themselves. First, what the most learned Christoph Rothmann replies to Scaliger on almost the same matter of comets, namely in his description of the comet of the year 1585, page 139: *"But truly,"* he says, *"my Scaliger, this Subtlety of yours — the honour with which you several times dignify Cardano's subtleties — deserves the whip. You insultingly call Homer, the best of poets and approved by all, a 'Greekling'; by what name shall I call you here?*

[Margin: Contra negantem principia non eſt disputandum.] *There is no disputing with one who denies the principles.*

But since there is no disputing with one who is ignorant of the principles, I shall first hand you over to the mathematicians to be taken in hand and instructed, so that you may learn from them what parallax is, and where it comes from. Once you have learned this, my dispute with you will be easy. Indeed, you will then acknowledge your error yourself, to the point of shame, nor will you deny that comets [?] the Moon cling in the spheres."

Likewise the advice which the most skilful Riccioli imparts to men of the same nature in Book VIII, On Comets, Section I, Chapter XVI, page 70 of the *Almagest*: *"We therefore advise these and men of this kind either to steep themselves in the doctrine of parallaxes, and only then to approach this judgement; or, if they*

are unwilling or unable to learn this doctrine thoroughly, to refrain from passing absolute judgement on matters they do not understand, lest they make themselves a laughing-stock to those who do understand.

[Margin: Abſolutum judicium, de Cometarum ſede, Aſtronomis tantùm competit.] *Absolute judgement on the seat of comets belongs to astronomers alone.*

At most, let them dispute about the nature and origin of comets on the hypothesis that it has been demonstrated by the mathematicians that all or some of them are above, or below, the Moon; but let them leave absolute judgement to the astronomers, and defer it to them as to men skilled in their own art — just as Aristotle, in matters that concern astronomy, judged that one should defer to Eudoxus and Callippus [Calippo], and appeal to them in cases of doubt."

[Margin: ConſiliumKeppleri pro hebetioribus.] *Kepler's advice for the duller.*

I also ask them to ponder the advice of the most acute Kepler, which he offers in his introduction, page 9, on the motion of Mars [de Motu Martis], to those who are not endowed with so lively a wit in astronomical matters: *"But whoever is too dull to grasp the science of astronomy, or too weak to believe Copernicus without offence to his piety, I advise to leave the school of astronomy, to condemn, if he likes, any doctrines of the philosophers whatever, and to mind his own affairs; to give up this wandering through the world and go home to cultivate his own little field; and, raising to this visible heaven the eyes with which alone he sees, to pour himself out with his whole heart in thanksgiving and in praise of God the Creator — certain that he renders God no less worship than the astronomer, to whom God has granted that he sees more clearly with the eye of the mind, and who is able and willing himself to celebrate his God over the things he discovers."*

[Margin: Autor,omnes genuinos Cometas in æthere extitiſſe, ſtatuit.] *The author holds that all genuine comets have stood in the aether.*

If our opponents, who fight so strenuously for the camp of Aristotle, observe all this well in future and submit themselves to this advice, I do not doubt that they will one day take on a milder temper, and much more readily agree with us entirely on this question; and that in the end they will concede of their own accord that genuine comets are not sublunary meteors but purely ethereal bodies.

For I am wholly of the view that not only the comet of the year 1652 but all the other true comets as well have stood in the heaven itself. If only our predecessors had left us more accurate observations of comets, from which this very point could have been derived, this dispute would surely have been settled long ago! But, regret- tably, apart from Tycho alone, almost no one has made sufficiently exact observations in this business of comets. We therefore earnestly ask each and every one who is thoroughly practised in this arena [in hoc pulvere; literally, in this dust] to direct their eyes and minds to comets more diligently in future than hitherto, and to measure them with every effort using the most approved instruments. Then it will be plainly evident that all comets move in the highest aether and are of almost the same nature as the

other, eternal planets, with this distinction: that they are only temporary, and as it were pseudo-planets, as will be said more fully in its place.

[Margin: Quoniam Veteres aliquantò negligentiores in deſcribendis Cometis extiterunt, Recentiores Poſteriq́; admonentur,ut diligentiores ſe ſe præbeant.] *Since the ancients were somewhat more careless in describing comets, the moderns and posterity are urged to show themselves more diligent.*

Meanwhile, however, I do not altogether deny that some comets also sometimes pass through the sphere of the Moon, indeed below it, not far from the Earth, as was absolutely the case with the comet of the year 1472. Indeed, I would rather concede that when they advance in the plane of the ecliptic, or are carried toward the Earth by chance, they can at some time graze it and strike into it with their body. But I would have you note that in that case they would appear to us not in the likeness of comets, but by night like a towering and huge fire, and by day like the densest murk. Kepler too holds the same in his *Physiology of Comets* [Cometarum Phyſiologiâ], p. 104, where he says: *Since, then, so many comets pass everywhere through the ethereal expanse, it is not unbelievable that some at times run into the Earth itself as well, and so graze the Earth, or, if they themselves are larger, are as it were pierced through by the Earth. But then they are not seen, as comets usually are, in the guise of a tailed star, but in the guise of a fire by night, or of a murk by day, which sometimes lasts no short time.*

[Margin: Poſſe Ccmetas nonnunquam infra Lunam incedere, imò ipſam Terram attingere.] *That comets can sometimes move below the Moon, and indeed touch the Earth itself.*

[Margin: Quâ ſpecie Cometa videretur, ſi Terram raderet ?] *In what guise would a comet be seen if it grazed the Earth?*

This very thing, which we have just asserted with Kepler, does indeed seem to be a paradox with respect to that assertion so often repeated, namely that no comet is sublunary. But if you rightly grasp our meaning, you will find that both can stand, and that we have by no means been deluded. [Margin: Cometa ſimul ætherem aërēq; nonnunquam trajicere poteſt.] *A comet can sometimes cross the aether and the air together.* For if any one of the comets, with a motion either straight or curved, were to cross the orbs of the planets in such a way that the path of its course passed between the Earth itself and the Moon, then that comet would certainly of necessity enter and pervade our sublunary air; and so it would consequently be rightly said that comets sometimes move even in the air itself, though for a short space of time (as cannot happen otherwise, because of its most rapid passage). But, so that you understand this well: it is one thing for comets arriving from the high aether to cross our air and make for the aether again; it is quite another for comets to be wholly generated and destroyed in the air, and to remain in it for the whole time of their duration, or to complete their course there. [Margin: Nullus Cometa generatur in aëre.] *No comet is generated in the air.* The latter we in no way concede, as will be established at length elsewhere; but the former can happen rather often. So it was observed by Cysat in the comet of the year 1618: namely, that at a certain

time it stood lower than the Moon, but only for a short space of time, so that it was neither born in the region of the air nor ceased to exist in it. On this the same author, in chapter III, proposition VIII, reports as follows about the same comet, p. 60: *The comet advanced in a straight line, such as M L represents; and since this cuts the heaven of the Moon, the comet passed through the outermost sphere of the Moon before December, so that it was perhaps 10 semidiameters nearer to the Earth than the Moon, and hence the least distance of the comet from the Earth would be about 40 semidiameters of the Earth. After 29 December, along the line M L, through the spheres of the planets, the Sun, Mars, etc., to such distances from the Earth, straight upward fled the com- et, so that no parallax could any longer be perceived with our instruments; and, unless it perished first, it pressed on all the way to the firmament.*

Now let us turn to some questions, inquiring first whether each and every comet, as certainly happened in our own comet, likewise departed further and further from the Earth day by day, and continually became higher. Answer: not all comets are entirely alike in this respect, although most have always risen higher from the first beginning of their appearance, as is to be seen in the comet of 1531, of 1585, of 1590, of 1607 and of 1618. But others, like the comet of the year 1533, were higher at first and afterwards approached the Earth more and more. Others were more remote from the Earth at the beginning and toward the end than around the middle of their appearance, as happened in the comet of 1532. The first are always swifter at the beginning of their path, and are afterwards found slower day by day; the intermediate ones are slower at first and swifter at the end; but the last are the swiftest of all in the middle. There can, however, be still others which would seem to vary very little, both in distance and in motion: namely, if they complete their course at a most remote distance from the Earth, through the orbs of the superior planets, Jupiter and Saturn, and indeed around conjunction with the Sun, where they are hidden again by the Sun's rays a little after their first rising, and stay before our eyes for only a short space of time. That all this is so, and also what the genuine reason for these things is, will become better and more clearly evident when we come to speak expressly of the motion and trajectories, to which I refer the reader.

[Margin: An omnes & ſinguli Cometæ à terrâ magis magisq́; removeantur ?] *Whether each and every comet recedes further and further from the Earth?*

[Margin: Singuli ferè Cometarum peculiarem motum exercent; & quâ ratione.] *Almost every one of the comets performs a motion peculiar to itself; and in what manner.*

Second: it is asked whether all comets have fixed bounds or limits of elongation from the Earth, and always recede by an equal interval and proportion. The answer is no. For just as each one of the comets claims for itself an entirely peculiar motion with respect to the regions of the world, both of the ecliptic and of the equator — now one, taking its rise in the north, directs its path toward the south; now another proceeds from east toward west; now another from west to east; now from the south it makes for the north — so likewise

in every comet something singular always appears with respect to its distance from the Earth as well. Now one, coming from a place in the aether far more remote than another, becomes nearer to the Earth; now again it flees to the most remote places. So no one of them all is ever entirely similar to another, neither in motion, nor in trajectory, nor in distance; nor, in our judgement at least, will any come into view in future that will not enjoy peculiar properties, if not in all respects, then at least in some. This very thing can be demonstrated without difficulty once all comets have been skilfully observed, and above all their parallaxes, and the distances derived from them.

[Margin: An omnes Cometæ æquale omninò intervallum à terrâ ac pari velocitate emetiantur ?] *Whether all comets traverse an entirely equal interval from the Earth, and with equal speed?*

[Margin: Nullus unquam Cometarum alter alteri prorsùs ſimilis extitit.] *No one of the comets has ever been entirely similar to another.*

For the comet of the year 1577, when at the start it was nearest to the Earth, had a parallax of 20′; around the middle, 2′ 46″; and around the end, barely 2′. Hence at the beginning it stood 173 semidiameters of the Earth from the Earth; around the middle of its appearance, 1257 semidiameters of the Earth; but around its exit, 1733 semidiameters of the Earth from us, as Tycho fully proved in Book II *de Comet.*, p. 206. The comet of the year 1580, moreover, almost surpassed Saturn in its remoteness, as the same author attests, volume 2, p. 442.

[Margin: Exemplis probatur Cometas diverſimodè à terrâ remotos fuiſſe.] *It is proved by examples that comets have been removed from the Earth in different ways.*

Again, the comet of the year 1585 reached as far as the sphere of the Sun, at the same page cited. But the comet of the year 1607, as Kepler holds on p. 6 concerning that same comet, was never nearer to the Earth than 449 semidiameters of the Earth; at its greatest elongation, however, of 4588 semidiameters of the Earth, it was removed far above the Sun itself. And finally the comet of the year 1618, according to Cysat's calculation, was carried up as far as the sphere of Venus, that is, to 252 semidiameters of the Earth; but according to Crüger, as is evident from his *Uranodromus Cometicus* [Uranodromo Cometico], chapter IX, p. 56, it exceeded 336 semidiameters of the Earth.

[Margin: Quot Semidiametris T. Cometa 1618 à Terrâ diſtiterit ?] *By how many semidiameters of the Earth was the comet of 1618 distant from the Earth?*

Indeed, if we put faith in Kepler, the same comet was plainly thirty times higher than the Moon right at its beginning: for he believes it showed a parallax no greater than 2′, p. 92, *Hist. Comet.* He adds besides in the same place: *At its first appearance it was in the middle space between the orbs of Venus and Mercury; from there it crossed the whole sphere of Venus; the whole space between the orbs of Venus and of the Earth; the whole sphere of the Earth, around 21 December; the whole space between the orbs of the Earth and of Mars; finally the whole orb of Mars, and it passed out into the space between Mars and Jupiter.* So he writes. From this it is clearly deduced that any comet now ascends more and more, now descends

more and more toward the Earth, unless it is hidden by the Sun immediately after its first appearance, or vanishes altogether.

Third: the question arises at this point whether the ascent and descent, or the elongation and approach, of comets with respect to us is entirely equal in all of them; or, what is the same, whether they keep similar degrees of speed and slowness at every time, and always complete their course in an equal interval of time. This, however, is altogether denied. For just as in their distances, so likewise in these respects almost every one of the comets displays something singular, so that none is ever similar to another in every part. For the further the line — the trajectory, that is — stands from the Earth, the more slowly they seem to move; conversely, the nearer the said line is to the Earth, the swifter their motion appears. Add to this that the motion itself, implanted in comets by nature, can greatly increase and diminish these degrees of speed and slowness, as will become more fully plain in its place.

[Margin: An unusquisq; Cometarum diverſos gradus velocitatis & tarditatis ſemper obtineat ?] *Whether each one of the comets always holds different degrees of speed and slowness?*

[Margin: Trajectoriam Cometarum penitùs eſſe inæqualem.] *That the trajectory of comets is altogether unequal.*

We shall show by the following examples that all this happens entirely so: namely, that the motion of comets, or their trajectory, is altogether unequal, and that comets are subject to one variation after another, indeed to almost infinite ones.

1. The comet of the year 1577 traversed 91° 46′ in its orbit from 9 November up to 25 January, that is, in 79 days; but in semidiameters of the Earth, 1560. For at the start it made 173 semidiameters of the Earth, and around its exit 1733 semidiameters of the Earth, daily. Hence it is rightly conjectured that it finally reached about as far as the sphere of Mercury.

[Margin: Exemplis convincitur. 1 Cometâ 1577] *It is proved by examples. 1. By the comet of 1577.*

2. The comet of the year 1585 traversed 39° 21′ in its path from the 18th to 15 November, within 28 days, so that it almost ascended to the Sun itself. Hence, indeed, it is concluded with certainty that this comet was much swifter than the former. Tych. *Ep.* p. 19.

[Margin: Com. 1585.] *Comet of 1585.*

3. It is certain that the comet of the year 1590, which Tycho mentions in *Epist.* p. 181, advanced 42° 10′ in its orbit from 23 February to 6 March, in only eleven days; and nevertheless it extended its trajectory as far as the Sun, indeed above the Sun, since no parallax at all was detected, as Tycho testifies, p. 179, *Epist. ad Landgravium*.

[Margin: Com. 1590.] *Comet of 1590.*

4. The comet of the year 1618, according to Cysat's calculation, from 1 December up to 22 January, in 53 days, although it completed about 85 degrees in the course of its path,

[Margin: Com. 1618.] *Comet of 1618.*

nevertheless barely reached the sphere of Venus; Kepler, however, maintains that it was carried forward as far as Jupiter itself, as you have already learned above.

5. The comet of the year 1607 crossed 97 degrees from 26 September to 26 October, in 31 days, and attained the distance of Venus at its apogee.

[Margin: [[C/G]]om. 1607.] *Comet [?] of 1607.*

6. The comet of the year 1652 completed its course of 65° 51′ in its proper orbit from 20 December to 8 January, in 20 days; on that day it had reached the orb of Mars, and on 9 and 10 January it had already entered the orb of Jupiter, as was demonstrated above, p. 317.

[Margin: Com. 1652.] *Comet of 1652.*

From this it is rightly gathered that each comet has a quite different motion: so that one traverses a larger interval of the heaven in a shorter space of time, while another covers a smaller path in a longer interval of time; one is now higher, now lower, now one lasts longer than another, and so on; so much so that in this respect too one gives way to another in a great many things. The chief cause of this, however, is that almost every one of the comets performs a singular daily motion, both swifter and slower. For the comet that shone in the year 1577 flew through 6° 2′ each day when it was swiftest; the comet of 1585, by contrast, completed only 2° 18′ with its daily motion; the comet of 1590, 7° 34′; the comet of 1607, 9° 40′; the comet of the year 1618, 3° 20′; and the comet of 1652 traversed 11° 16′ in one day. And from this we again find that the daily motion of all comets varied successively: in most it decreased little by little, but in some, conversely, it grew from day to day, as we have already often insisted.

[Margin: Vnusquisq; Cometarum aliquid ſingulare ſibi vendicat; & quare ?] *Each one of the comets claims something singular for itself; and why?*

[Margin: Motus Cometarum diurnus diverſisſimus eſt.] *The daily motion of comets is most diverse.*

But where such a diverse diversity in the decrease and increase of the speed of motion arises from; why this daily motion is not always uniform and equal; likewise whether some regularity, or rather an irregularity, is found in this inequality; and above all why the daily motion is so in some comets at the beginning, in others around the middle, in some around the end, and in some even entirely the contrary: all this, together with many things worth knowing, we are not yet able to explain and demonstrate on this occasion. It must be deferred until we come to unravel the rectilinear and curvilinear motion.

[Margin: An inæqualitati motus diurni aliqua etiam inſit regularitas ?] *Whether some regularity also belongs to the inequality of the daily motion?*

Nothing therefore remains at this point except to add to this Book a small table, in which everything we have said above about the various distances of certain comets from the Earth, their duration, their motion in their proper orbit, and also their greatest daily motion, is set out as if at a single glance.

[Margin: Quorundam Cometarum diſtantiæ duratio & motus exhibentur.] *The distances, duration and motion of certain comets are shown.*

A small table showing the distances of certain notable comets from the Earth, their duration, their motion in their proper orbit and also their greatest daily motion. [Tabella, quorundam inſigniorum Cometarum diſtantias à terrâ, durationem, motum in propriâ orbitâ tum diurnum maximum, oſtendens.]

Comets	Distance from the Earth, S. T.	Duration, days	Motion in its own path (Deg., Min.)	Greatest daily motion (Deg., Min.)	Observers
1577	least 173 S. T.; greatest 1733; as far as the sphere of ☿ [Mercury]	79 days	91° 46′	6° 2′	Tycho
1580	reached higher than ♄ [Saturn]				Tycho
1585	as far as the Sun	28 days	39° 21′	2° 18′	Tycho
1590	was higher than the Sun	11 days	42° 10′	7° 34′	Tycho
1607	least 449; greatest 4588; as far as the apogee of ♀ [Venus]	31 days	97° 0′	9° 40′	Kepler
1618	as far as the sphere of ♀; 252 S. T.; 336 S. T.	53 days	85° *circ.*	3° 20′	Cysat; Crüger
1652	on 20 December, 110; on 8 June, 10311; was above ♂ [Mars], and on the 10th in the sphere of ♃ [Jupiter]	20 days	65° 51′	11° 16′	Hevelius

534

Johannes Hevelius, Cometography, Book Six [JOHANNIS HEVELII COMETOGRAPHIÆ LIBER SEXTUS.]

On the Apparent and True Size of the Head and Tail, and on the Light and Colour, both of the Comet of the Year 1652 and of Certain Other Comets [De viſâ & verâ magnitudine Capitis & Caudæ, Lumine & Colore, tam Cometæ anni 1652, quàm aliorum quorundam Cometarum.]

[Margin: Genuina facies Capitis caudæque Stellæ Crinitæ an. 1652.] *The genuine appearance of the head and tail of the hairy star of the year 1652.*

Before we come to the point of being able to compute the true size of the head and tail of our comet of 1652, it is useful first to set down here a particular description of the face with which the head presented itself to our view, both on the first day and on each of the following days. From our general account you have, no doubt, already understood well, if briefly, what we related about this phenomenon: that it had a round body of rare size (namely, on December

[534] in the 1652 row the table prints *Junii*, June, for the 8th; the text above gives this comet's course as running from 20 December to 8 January. The figures 110 and 10311 in the same cell stand as printed.

20), scarcely somewhat smaller than the full Moon; a remarkable and long tail, or beard, of six or seven degrees, directed toward the belt of Orion and the east, that is, turned away from the Sun, and stretching through the star above the foot of Orion, which shone out very brightly in it, almost as far as the star in the hilt of the sword; and that the light of the head was pale, and in part dull, and less splendid, like the Moon covered by a very thin little cloud; while the light of the tail itself, which tapered to a very thin point, was almost rarer still.

[Margin: Dubitat Autor Philoſophos Peripateticos huic obſervationi fidem adhibituros.] *The author doubts that the Peripatetic philosophers will give credence to this observation.*

That these things truly appeared — namely, that its head was not smaller than the body of the Moon, whose diameter contains about 30′ — will scarcely be believed by those who were not given the opportunity of seeing the comet; especially if they examine somewhat more exactly for themselves how great a body that must be whose diameter is given as 30′, not to mention what follows if a comparison is made with the other planets and ethereal bodies. But indeed I frankly confess myself that at the first sight, in the evening at 7^{h} and 8^{h} on December 20, I marvelled not a little at that unusual torch, and indeed stood still, astonished at the novelty of the thing. Truly, had I not watched the comet with these eyes of mine, together with certain learned men who were with me then and were assisting me in the observations, I myself would refuse those things belief. But how much more contrary to reason will it seem to those who are ruled by the preconceived opinions of the Peripatetics, and that comets, out of pure vapours and earthy exhalations, con- sist, contend? Will they not object that even the whole terrestrial globe would in no way suffice to evaporate so much matter? And what of this: that even if the whole globe were resolved into vapours, a body of such astonishing size would still scarcely coalesce out of them?

[Margin: Vt ut nonnulli fortè aliter ſentiant, Cometa tamen Lunam magnitudine ſuperavit.] *However some may perhaps think otherwise, the comet nevertheless surpassed the Moon in size.*

But however much some may judge it far smaller, I nevertheless bid you rest assured that the comet did indeed equal the Moon. In fact, had I measured that phenomenon properly with an instrument, or with some tube, I do not doubt that it would have exceeded the disc of the Moon by a notable amount. Do not suppose, however, that I failed altogether to distinguish that spurious light from the true body, and seized on all the adventitious rays as the true head of the comet. For I would have you know that the whole head of this phenomenon had an even light, not diffusing about the limb but bounding an exact circumference; so that to the naked eye it could not be seen otherwise than as having no livelier light in the middle, except for certain nuclei, like little spots, which could be seen only through the telescope [perspicillo]. This I found more than amply with our larger telescope after some days had passed, as you will soon learn at greater length.

[Margin: ColorCometæ.] *The colour of the comet.*

The colour it displayed, however, was somewhat darkish, dusky and gloomy; not as lively as that of the fixed stars and the planets, but paler still than the light of the Moon itself, although comets are mostly seen glowing red, fiery, and with a twinkling light. Yet it did not show this colour entirely the same at all times; of which more fully below. It is now best to set out first, together with my own, the notes of certain most distinguished observers on this comet, its size and its colour, so that you, judicious reader, may proceed more safely, and that both these reports of mine and what is contained in the general description may earn all the greater credence with you. Above all, since the observations were made and published in different and very remote places, by different observers, with no prior communication, the truth may thereby become known all the more clearly to posterity, to the greater benefit of learning.

[Margin: Wendelini obſervatioCometæ anni 1652.] *Wendelen's observation of the comet of the year 1652.*

1. Govaert Wendelen, a man of remarkable learning, describes this phenomenon in his *Teretologia Cometica* in these words, p. 25: "On December 20, at Tournai [Tornaci], around the eighth hour after noon, my household, going to the neighbours on domestic business, noticed in the sky an unusual but dark light, as of the Moon hidden behind a cloud and shining faintly, etc." Likewise pp. 26 and 27: "On the 21st, at the eighth hour of the evening, I see (he says) near the shield of Orion an unusual light, which was indeed larger than any of the nebulous stars, but shone more faintly, with a pale, boxwood colour, gloomy and dark. And since I knew there was no nebulous star in that place, I perceived, on fixing my gaze more closely [?], that it was in truth a comet, but of a different kind from those I have reviewed and remember having observed. Its size (take note) was such that it either equalled or exceeded the disc of the Moon, etc." (He adds besides in the same place:) "The younger of my nieces, who the day before (as I related above) had seen this new prodigy near the neighbours' houses, added that it had then been much larger, and also of a livelier colour, whereas now it was pale and of a boxwood colour; those who had been present affirmed the same."

[Margin: Cornelii Malvaticæi de eodem Cometâ obſervatio.] *Cornelius Malvaticæus's observation of the same comet.*

2. The most illustrious Cornelius Malvaticæus detected this portent at Bologna [Bononiæ] in almost the same appearance. "At the first hour of the night (namely, by the Italian clock)," he says in his observation published at Padua [Patavii], "on December 21, a comet was found near the stars of the shield of Orion, nebulous and of remarkable size, its diameter almost equal to the semidiameter of the Moon. Through the telescope the whole body did not appear to be of the same character. For in the middle it bore a whitish disc, as the Moon is seen among clouds; and it was as large as the Moon itself appears to the naked eye (note well), and even somewhat larger."

[Margin: D. Chriſtiani obſervatio ejusdem Cometæ.] *D. Christianus's observation of the same comet.*

3. At Giessen [Gisſæ Cattorum] the most learned D. David Christianus (as is evident from his little *Physico-Astronomico-Historical* work, p. 8) recorded it thus on December 8, Old Style: "I noticed (he says) a new phenomenon and an adventitious star, endowed with a dark, rare and nebulous light, which in its whole form was very like that cluster, or heap and conglomeration of stars, which they call the Pleiades; except that from the beginning, around this day and some following days, it seemed somewhat larger than that very cluster (note: for the Pleiades themselves occupy a space of almost one degree in the sky), so that if anyone looked more accurately at its very extremities, it would very nearly equal in apparent size a small disc a span [ſpithamam] in diameter; although, because of the gloomy aspect of its dull light, it by no means presented itself to the eyes as clearly as the planets or the fixed stars, coeval with the world."

[Margin: Obſervatio Cometæ an.1652, Alepi habita à Baſirio.] *Observation of the comet of the year 1652, made at Aleppo by Basirio.*

4. To these three I shall add yet another very notable observation, made in a very remote place, namely at Aleppo [Alepi], by a most excellent physician, an Englishman, that is, Doctor Basirio, if I remember rightly, who described this new phenomenon in almost the same words as ours; at which I marvelled not a little. For he agrees with us so remarkably that you would have sworn that observer had extracted all of it from my notes; which, however, as I know well, never happened, nor perhaps has he ever yet seen anything of mine. The observation itself runs as follows: "On the twentieth day of the month of December of the year 1652, at about the eighth hour of the evening, in the city of Aleppo [Alep], which is in the province of Commagene in the kingdom of Syria, a comet was seen, very notable and of unusual size, for it almost equalled the Moon; somewhat pale in colour, resembling a little cloud lit by the Sun, roundish, yet pointed toward the east and as if bearded. It was first seen in the sign of Gemini, near Regel, or the foot of Orion, at the very beginning of the river Eridanus, making an equilateral triangle with the said Regel and the star at the right leg of the said Orion."

[Margin: Obſervationes inter ſe egregiè conſentiunt.] *The observations agree remarkably with one another.*

I could add more observations of this kind, if there were need, but these, I think, suffice; and from them we have it established clearly enough, and beyond doubt, that I have put forward not dreams and fictions but the very truest things. Nor, surely, could it ever have happened that four different observers, separated from one another by very great distances, one living in Europe, another in Asia, holding entirely different conceptions and possessing different keenness of sight, who never communicated with one another about this matter, should agree so precisely in everything? Truly, unless the matter rested on the naked truth, you would have looked in vain for observations so alike. All of them,

therefore, saw along with me the co- met, on December 20, with exactly the same face: namely, that its head not only approached the size of the full Moon but very nearly exceeded it by a little; likewise, we agree very well among ourselves about its light, its colour and also its beard.

[Margin: CaputCometæ indies decrevit, lumenq́; obſcurius extitit.] *The head of the comet decreased from day to day, and its light became darker.*

On the following days, however, the phenomenon did not keep so great a size steadily; for, as far as the naked eye could tell, it at once decreased very greatly. On December 21 and 22 it was not possible to view the comet at all, because the air was thoroughly turbid; but on the 23rd, although it had by then notably diminished, I nevertheless examined it several times that same night with very large brass instruments, and found that its disc still measured about 25′, 27′ and more. The tail, however, it showed of only 5°. The light and the colour, too, of both the head and the tail appeared much duller and gloomier, almost like those of a nebulous star, although the body itself was still very conspicuous among the other stars.

On December 26 it had decreased more and more; yet the head, as was judged by means of the instruments, still measured 24′ or 23′ in diameter, while the tail appeared only two degrees long.

[Margin: Quali facie Cometa per Teleſcopium apparuerit ?] *With what face did the comet appear through the telescope?*

On December 27, although it had become still smaller and weaker, it nevertheless presented itself very well to view among the stars. The length of the tail was estimated at 4°. Moreover, since the sky favoured us exceedingly that night, I also examined that cometary body with a certain very long optical tube, which among other very distant objects distinctly reveals even the companion of Saturn. With this telescope, however (which otherwise takes in [obtendit] 20′ and more, from which its diameter may roughly be inferred), I could not take in the whole disc. It spread a very dull and feeble light, and in the disc itself, toward the left and toward the tail, it showed four or five small bodies, or nuclei, somewhat denser than the rest of the body, of which two seemed a little larger than the other three; although several other very tiny ones besides presented themselves, scattered here and there in the disc, which nevertheless almost eluded the sight, so that it was not possible to distinguish and draw them properly. Toward the right, however, we noticed a winding and twisting light, much brighter than the rest of the whole body, just as if it were a heap of many very tiny small bodies. Yet this light was not so intense and lively as that of the other fixed stars or of the planets, but a little duller.

[Margin: Obſervationes diei 29 Decem. & ſequentium.] *Observations of December 29 and the following days.*

On the morning of December 29, because the air was full of vapours, we could scarcely make out even the head, let alone the tail, especially since it stood only 14° or 12° above the horizon.

On the evening of December 30 the body, together with the tail itself and the light, had decreased more and more.

On the morning of the 31st it was still decreasing; but the tail, because of its low position with respect to the horizon, did not shine out anywhere at that time.

On January 1 of the following year the comet, as also its tail, was a little brighter, because the sky was very clear.

On January 2 it had indeed diminished still further, but it was nonetheless still quite notable in size: for in diameter 7 or 8 minutes [minuta prima] was what it measured; but its light appeared very weak, like that of some nebulous star.

On the evening of January 3, with the sky very clear, the comet once again, and its tail too, 2° in size and stretching toward the belt of Perseus, presented itself quite distinctly to the eye.

On the morning of January 4 the head was seen just as well as on the previous day, but the tail more dimly. On this occasion I noticed that the tail of this comet always appeared brighter in the evening than in the morning. The reason is this: in the evening it always hung high in the sky, beyond the vapours and the refraction, whereas in the morning it stayed near the horizon, exposed to refractions, and was, as it were, smothered by the vapours.

[Margin: Cauda hujus Cometæ ſemper clarior tempore veſpertino quàm matutino apparuit.] *The tail of this comet always appeared brighter in the evening than in the morning.*

But on the evening of January 6 it could be found nowhere in the sky, because of the presence and brightness of the Moon. On the following morning, the 7th, it did come into view again, though without its tail, which from January 4 onward had vanished entirely because of its extreme rarity; the size of the head was estimated at about 5′.

On January 8 it was still much thinner and rarer, so that it could barely, or not even barely, be made out even with keen attention, not even by those whose sight was otherwise strong.

On January 10 it withdrew itself entirely from the naked eye; but to those armed with a longer telescope it still showed itself to some degree. We therefore found it further attenuated still in respect of its head and its light, yet in size far exceeding the fixed stars, even those of the first rank. Its little body, however, was extremely rare, so much so that no nuclei at all appeared in it any longer: for the matter seemed scattered and very much diluted, just like a shadow, with certain fissures and passages interspersed. All of this, however, was made out with difficulty and [?] equally accurately [difficulter æq; accuratè], as usually happens with spots that are just about to perish.

[Margin: Die 10Januar. 1653 Cometa ultimò obſervatus, & quâ ſpecie.] *On January 10, 1653, the comet was observed for the last time; and in what appearance.*

Month	Day	Apparent diameter of the comet (Min., Sec.)	Month, day	Apparent diameter of the comet (Min., Sec.)

535

From these figures, then, we rightly gather how large its apparent diameter was, not only on December 20 but also on each of the following days right up to its extinction: that is, how it decreased day by day in respect of its head, its light and its tail. You will learn all of this still more perfectly, however, from this little table and the accompanying diagram [Schemate]. In the little table you will have the size of the diameter in numbers; in the figure [Schematiſmo], however, the actual proportion of both the body and the tail, and also its head in a somewhat larger aspect, as it was perceived with the telescope on the 27th.

[Margin: Apparens Cometæ diameter quotidie variata eſt.] *The apparent diameter of the comet varied daily.*

[Margin: Genuina Cometæ 1652 effigies.] *A genuine likeness of the comet of 1652.*

Diagram. An engraved plate across the full width of the text block, below the paragraph above. On the right is the comet's round head, edged all round with a fringe of short rays; its disc is hatched with horizontal lines and carries small dark dots and a lighter curving band. From the head's left side a tail of fine crossing lines streams to the left, broad at the head and narrowing toward the plate's left edge. The plate's only inscription is the engraver's signature at its upper left, in a cursive hand, set upside down relative to the text:

- Upper left (inverted): "Autor ſculpsit" — "The author engraved it."; the mark after it is not settled between a full stop and a comma.

No letter, number or other label is engraved on the plate.

Here I should like you to note that it was not only I who noticed these little stars, or nuclei, visible in the disc, but that other distinguished interpreters of the heavens, men able to grasp the nature of things, did so as well as I. Govaert Wendelen informs us of this in his *Teretologia Cometica*, p. 25: namely, that

[535] the table is set in two blocks side by side within a ruled frame. The right block's single column headed *M. D.* holds month and day together. The month is printed only in the first row of each block. Rules divide the rows into groups of three.

the Jesuit Fathers at Mantua observed several stars in the comet. He adds in the same place, on p. 27, that he himself noted quite distinct, very tiny little stars in it. "(For) at the eighth hour," he says, "the comet stood at the lower part of Orion's shield, forming a triangle with the seventh and the eighth star in it, and as it were the boss of that shield, somewhat nearer to the eighth star than to the seventh. But when I go down into my study, get my telescope ready and examine the whole body of that star for some time, I see in it a good number of very tiny little stars, and among them one larger than the rest and oblong, in the middle of the others: you would have said it was some hearth, its wood burnt up, showing its remaining embers with live coals and sparks mixed among them. In short, its face seemed to me the same as that of the earlier comet seen in the year 1618 in the hand of Bootes." So he writes.

[Margin: Caput Cometæ ex nucleis ſive Stellulis conſtitit.] *The head of the comet consisted of nuclei, or little stars.*

[Margin: Idem Cl.Wendelin. animadvertit.] *The distinguished Wendelen noticed the same.*

Perhaps there are more people still, lurking here and there, who saw the comet in this way just as we did; but of them nothing whatever has so far been reported to me, nor have I learned anything. Meanwhile I do not doubt at all that whoever has had a telescope simply of good quality, and has directed his eyes and the tube at the phenomenon, will have found everything really to be so. That very few are found who attest the same things comes about because very few gape after secrets of nature of this kind and take delight in them; and if by chance one or another is still found, they mostly lack telescopes [Tuboſpicilla] capable of celestial things. For instruments of that kind are not on sale in every market, nor are they so easily polished and constructed by any craftsman you please. Add that those who belong to the Peripatetic school, even if they have some telescope at hand, prefer to keep away from that business rather than look into those portents a little more attentively, since they have already firmly settled in their own minds that these are earthly exhalations; they fear that their own eyes might perhaps lead them to doubt, or even to settle on the contrary. Exactly the same thing happened in Italy, as the most celebrated Ismaël Boulliau, our very great friend, reports in a letter written to me in the year 1648 on December 11 [die III. Idib.Decembris]: namely, that at Florence, while he was staying there, there was a physician to the Most Serene Grand Duke of Tuscany, utterly devoted to the Peripatetic philosophy, who at all times absolutely refused to look with his own eyes through the telescope at the bands and spots of Jupiter, fearing that he would be thrown into confusion in his Aristotelian philosophy and in his once-preconceived opinion, or at least be made doubtful. But hear rather the author's very own words: "Further, concerning Jupiter," he says, "what you report became plain to me as true with the tube which the Grand Duke of Tuscany gave me as a gift; and I agree with you. Not only do your observations not allow the surface of that planet to be perfectly smooth, but those which the Most Serene Prince made with

that very long telescope discovered spots on the surface of the body of Jupiter. The school of the Peripatetics, thrown into disorder and defeated by these new experiments, trembles throughout the whole world. But those who have followed its party, so as not to be convicted of treason, refuse to cross over to the camp of truth and shut their eyes; nor

[Margin: Quare non cuivis illud ipſum phænomenon obſervare concesſum fuerit.] *Why not everyone was granted to observe that very phenomenon.*

[Margin: Peripatetici ne turbentur in præconceptâ opinione, obſervationes detrectant.] *The Peripatetics refuse observations, so as not to be disturbed in their preconceived opinion.*

[Margin: Cujus rei exemplum Celeb. Bullialdus in Epiſtolâ deMedico quodam Magn. Duc. Hetruriæ profert.] *The celebrated Boulliau, in a letter, gives an example of this, concerning a certain physician of the Grand Duke of Tuscany.*

[Margin: Litteræ Iſmal[[./,]] Bullialdi.] *The letter of Ismaël Boulliau.*

do they bring themselves to raise them and arm them with the tube, so as to put to flight the vain opinions they have formed beforehand. Take one example for all: a certain Florentine physician, whose services and counsel the Grand Duke uses, and whom he could never induce to look through the telescope himself at the things that, when others reported them, he regarded as trifles. And the physician alleged no other cause or reason to excuse his stupidity, except that, since he adhered firmly to the dogmas of Aristotle and did not wish to depart from them in the least, he feared he would be thrown into confusion by what was put before him; and he dreaded that reasons would be offered him not only for doubting the truth of the Peripatetic doctrine, but also for abandoning it. They do not allow themselves to be persuaded that the Sun is a true and real fire, because their leader [coriphæus] Aristotle, in the books *On the Heavens* (if indeed that inept and insipid work was published by him), asserts that heat is generated by the spheres rubbing against the air."

[Margin: Libros Ariſtotelis de Cœlo ſuppoſititios eſſe, putat Bullialdus.] *Boulliau thinks that Aristotle's books On the Heavens are spurious.*

From this preconceived opinion, I think, it has come about that most of the Peripatetics, although some of them clearly saw the comet at as great a size as was reported above, were nonetheless in no way able to persuade themselves that it had really grown to so great a size: for, once this was granted, their whole philosophy would be overthrown, and many absurdities would take their origin from it, as below, at greater length. For this reason those who follow Aristotle, and are led by authorities rather than by reasons, have preferred to contract the comet's diameter a little rather than to extend it too much. Indeed, so far as I know, not even one of them has appeared who agrees entirely with us, and with the observations above, on its size. Perhaps they thought it was only an adventitious light that had spread itself so widely in a ring; whereas it in fact had a light uniform over the whole disc, so far as the naked eye could judge, as we have already touched on. Others perhaps, for that reason too, deliberately described the comet as somewhat smaller, so as not to seem to go

altogether beyond the limits of comets and to report a portent quite unheard of until now, of a kind that had never appeared either in former times or in our own.

[Margin: Peripatetica Philoſophia planècorrueret, ſi tantamCapitis magnitudinem Cometæ adſcribas.] *The Peripatetic philosophy would collapse entirely if you were to ascribe so great a size of head to the comet.*

But in truth I would have you know, kind reader, that there have at times been comets, though very rarely, of no less immense and astonishing size, and therefore quite remarkable above the rest. For example: first, the comet of the year 400 after the birth of Christ, which Sozomen mentions, Book 8, chap. 4. 2. In the time of the Emperor Maurice, according to Niceph., book 18, chap. 35. 3. In the reign of Charlemagne, namely in the year 814, as the annals of France have it. 4. In the year of Christ 945, under Otto I, as Ludovicus Lavatherus [Ludwig Lavater] reports. 5. In the years 1101, 1106 and 1169, etc. Likewise, in the year of Christ 1200, Haly Ben Rodoan [ʿAlī ibn Riḍwān], when as a young man he was studying astronomy, saw a comet whose solid part appeared three times larger than Venus, and of round shape; and its light, he says, was as great as a quarter of the Moon: Book 2 of the *Quadripartitum*, chap. 9; Cardanus [Girolamo Cardano], text 54. Cardano likewise asserts that in the year 1268 a comet of wonderful size was seen in Scotland for several days around midday (a truly great marvel of a portent). 6. In the year of Christ 1444, Joh. Prætorius relates, a huge comet appeared at the time of the solstice, which terrified mortals. 7. In the year 1556, at the beginning of March, a comet was seen nearly equal to half the Moon, according to Cardano, Book 4, chap. 69, *De varietate*.

[Margin: Et olim immenſæ magnitudinis apparuiſſe Cometas, exemplis probatur.] *That comets of immense size appeared in former times too is proved by examples.*

[Margin: Cometa triplo majorVenere.] *A comet three times larger than Venus.*

[Margin: Cometa æqualis Lunæ dimidio.] *A comet equal to half the Moon.*

These examples clearly confirm that very large comets were seen long ago as well; yet, I admit, both the ancients and the more re-

[Margin: Lunæ autem æqualis nullus Cometarum niſi anni 1652 extitit.] *But no comet has been equal to the Moon except that of the year 1652.*

cent writers record none that reached the size of the Moon in diameter, let alone exceeded it. This, however, I think came about because praiseworthy antiquity, and above all the astronomers themselves, devoted very little careful effort to these matters and neglected much, supposing, that is, that comets were meteors and aerial bodies. Meanwhile, however, Seneca describes one (*Natural Questions*, Book 7, chap. 15) which shone in the year 146 before the birth of Christ, and whose diameter was no smaller than the diameter of the Sun or of the Moon: "After the death of Demetrius, king of Syria," he says, "whose children were Demetrius and Antiochus, a little before the Achaean War, a comet blazed out no smaller than the Sun. At first it was a fiery and ruddy orb,

giving off a light bright enough to overcome the night. Then little by little its size was drawn in, and its brightness faded. Finally it vanished entirely."

[Margin: Cometa non minor Sole illuxit.] *A comet shone no smaller than the Sun.*

It is therefore manifest that in former times too, besides this one of ours, there have been comets of wonderful size; indeed, comets that were much more distinguished in brightness and far more splendid. Yet we cannot deny that such immense and very large phenomena have been rare birds: for, except for these two, you will hardly ever produce another comet that equalled them in respect of the head, much less surpassed them. As for the tail, however, you will find countless ones; indeed, the greatest part of them far outdid ours. And so, again and again, the said comet is on that account rightly numbered among the rarest and most outstanding portents of the world, as much for the size of its body and its distance from the Earth as for its trajectory, so that it deserves not only to be well noted but also to be accurately described by us.

[Margin: Præter duos adeò admirandæ, quoad caput,magnitudinis, nullus unquam apparuit.] *Apart from two, none has ever appeared of so wonderful a size in respect of the head.*

[Margin: Cometa 1652 admirandum prorsùs & inſolitum fuit oſtentum.] *The comet of 1652 was an altogether wonderful and unusual portent.*

Moreover, it is established that not every one of the observers always observed the tail of the comet of the year 1652 as alike and the same in respect of length. This came about, first, because not everyone enjoys the same sharpness of sight: some make things out only when their eyes are brought closer, and are almost blind to things far off, like the short-sighted; others, by contrast, see and judge things set rather far away more easily and distinctly. For this reason not all these various observers found the comet to have had a similar tail. Second, because some perhaps noted the tail in the evening, with the Moon absent, at which time, as we have already touched on, it always appeared somewhat longer and clearer; while others drew the tail in the morning, with the Moon shining, when the comet stood lower, among vapours and refractions, and perhaps also with the air not entirely cleared: at which time the tail is mostly seen smaller and weaker. For in respect of such different positions, and of the state of the air, the comet always seems, as it were, to change its face and its tail (although the tail can also be changed in reality; but we are not speaking of that on this occasion, and it is left to its proper place). Tycho too perceived this very well in the comet of the year 1577: for in Book 2, chap. 9, p. 205, he says: "The apparent length of the tail showed itself in various ways according to the nature of the intervening air, and did not seem to keep a fixed tenor." Cysat noted the same in the comet of the year 1618: namely, that at times even the whole comet can be swallowed up by the vapours, just as happened with ours, that is, when it stood in the western quarter; as one may read in the same author, chap. 7, p. 77, in his description of that comet: "Why," he says, "in the western quarter, that

[Margin: Cur omnes & ſinguli obſervatores, eodem tempore non ejusdē magnitudinis caudā deprehenderint in Com. 1652?] *Why did not every one of the observers find the tail of the same size at the same time in the comet of 1652?*

[Margin: Cauda pro ratione aëris intermedii variatur.] *The tail varies according to the nature of the intervening air.*

[Margin: Cometa quando viſum illudat.] *When a comet deceives the sight.*

is, when it is near the horizon, is the comet not seen? Plainly, it is smothered and extinguished by the vapours, like other nebulous stars; for their rays, weak and most of them secondary, cannot penetrate the denser vapours around the horizon."

Moreover, that the matter stands entirely so — namely, that for the reasons given the tails can vary in different ways, so that even learned men, not to say the unskilled, can easily be deceived in determining and depicting tails — was also maintained by the most learned Marcus Squarcialupus, who discusses it elegantly in his little work on comets, pp. 41 and 42. I shall gladly set down his very words here: "I think, Dudith," he says, "that it cannot be that one and the same comet shows only one colour everywhere. And if the appearance of a comet is uncertain, judgement about the comet will always be suspect. For not only the stars and the hairy stars, but the Moon herself, and the Sun likewise, show various colours according to the varying state of the air. In the highest heaven, when the air is serene, the stars shine and gleam with a certain silvery brightness. If cloud or smoke fills the sky, the air is thickened, and we see the stars through smoke and vapours (which, however, we do not make out at night). Therefore their face appears darkish or reddish. And that is the reason why in summer we see the Moon and the Sun reddening on the horizon. Since, then, the inconstancy of the air is great, as there is not just one condition of sky and winds, I hold [?] that the definite face of a comet, that is, its true colours, can scarcely be made out. What then? Do not different situations of places always have different air? Mountains have a pure sky; valleys an impure and foul one. Dry ground makes the air thin, but wet ground and marshes make it thick, dense and foggy. We have a striking example this year. In the mountains the comet appeared bright, its gleam and splendour plainly silvery, especially in the coma. And Cornelius Gemma calls it bright, silvery, shining most purely. Fabricius, too, the Emperor's mathematician, writes that it was white shading into yellow, bright, and not terrifying. And yet a certain man distinguished for his varied learning, whom you know, writes that it was pitch-coloured, blackish, and like a torch seen through smoke. When I read these words I stopped short in astonishment, until the cause of this appearance occurred to me: namely, that the comet's colour was seen as black because of the thicker air of the place. For in a valley, a marshy place and always *luculento* [?], where Auster [the south wind] and the two winds on either side of it prevail, and which Aquilo, Boreas, Caurus and Favonius do not reach, the air deceives the sight, so that it presents to the eyes squalor in place of gleam, a fiery redness in place of splendour, and a dark, leaden colour in place of brilliance. A sky of

this kind often deceives not a few. And if we see philosophers slip, what will become of the unskilled and the inept, who are by far the greater part? And if the colour of the very great and most brilliant comet (namely, of the year 1577) deceived many, what will be certain in smaller and less bright ones?" Snellius, *de Comet.* p. 34, agrees excellently with this: "We see the tail," he says, "the appendage of comets, not in cloudy weather but in the most serene air, and indeed the larger, the clearer the air itself is." No wonder, then, that observers fixed the tail of our comet too in different ways — a tail that was certainly much duller than that of the comet of the years 1577 and 1618!

[Margin: In delineandis Cometar. caudis, & defcribendis coloribus etiam Viri exercitati nonnunquam facilè hallucinantur.] *In delineating the tails of comets and describing their colours, even practised men are sometimes easily deceived.*

[Margin: Varius aër, varium phænomëni colorem inducit.] *Varying air produces a varying colour in the phenomenon.*

But let us go on to inquire for what further reason the tail appeared to this or that observer now longer, now shorter, now brighter, now duller. Because, third, not all (as I judge) the true of seeing and dis- tinguishing the rarer and darker tails have kept to a method. But, you will say, is some special skill needed to carry out these observations? I should have thought that all who have strong sight could discern tails perfectly well. Most certainly, I say: this business must be approached cautiously and with a certain definite skill. If you do so, believe me, you will see the rather rare and duller tails of comets, and also the smallest and more nebulous fixed stars, far more distinctly, and you will find more quickly in the sky things otherwise scarcely perceptible to the sight. Whoever, therefore, has set out to observe such very thin and very rare bodies in the aether should contemplate those duller objects not with eyes directed fully at them, but with eyes partly oblique, as it were, as if he were directing his gaze to the neighbourhood of the thing. In this way you will certainly find not only that those bodies, otherwise invisible, strike the eyes more readily, but also that you can discern them much more clearly and perfectly — especially those feebler tails: towards what quarter of the sky, that is, and towards what stars they direct and cast them — than if you tried the thing itself with a more direct and quite intent gaze. Aristotle himself saw this well long ago; for in *Meteorologica*, Book 1, chap. 6, 330, he says: "One of the stars in the hip of the Dog had a coma, though a faint and dim one. Those who looked at it with intent eyes found its brightness slight, while those who cast their glance at it gradually, as if in passing, found it rather large." Kepler admits the same in the *Physiologia Cometarum*, p. 117, where he discusses the comet of the year 1607: "At first," he says, "when the tail was of faint light, I could not see it because of the weakness of my eyes; others, however, saw it. For it was not the tail that revealed the comet to me, but the size of a star in a place where I knew there was no fixed star so large. In the morning, however, turned straight upward, it was clear enough. I noted, however, that the tail appeared better with the eyes

directed beside the comet, into its neighbourhood, than if I had looked straight at the head."

[Margin: Quâ ratione obtuſiores & rariuſculæ Cometarum caudæ, minutisſimæq; fixæ accuratè cognoſcantur & deprehendantur.] *How the duller and rather rare tails of comets, and the smallest fixed stars, may be accurately recognised and detected.*

[Margin: Obliquis oculis diſtinctiùs nonnunquam objecta,quàm directis videntur.] *Objects are sometimes seen more distinctly with oblique eyes than with direct ones.*

Various reasons for this are ready to hand. For it is certain and established that the pupils dilate and contract according to the greater or lesser light that strikes or enters the eyes, and also that with the pupils somewhat dilated everything is seen and recognised far more distinctly than with them more contracted. Therefore whoever strives to look at a comet and its paler tail, or any faint object, somewhat obliquely — directing the eyes, that is, to the surrounding aether, towards the darker parts of the sky, as if to avoid letting that light of the phenomenon fall straight into the eyes and contract the pupils more than is right — he, I say, sees more clearly and exactly than someone who looks straight at the comet. For while the latter's pupils are narrowed too much, he is able to grasp or perceive by sight much less, because of that more intense and stronger light: as happens to those who fix their eyes too long on the Sun, a fire, or snow in winter, and who afterwards are half-blind, as it were, to paler and very small things. But before we bring forward anything more about tails, it will be worthwhile to continue with the subject once taken up above, and further to inquire into and compute properly the exactly true size of the adventitious body and its bulk.

[Margin: Ratio, cur ex obliquo adſpectu res nonnunquam clarior & diſtinctior appareat.] *The reason why a thing sometimes appears clearer and more distinct when looked at obliquely.*

[Margin: De genuinâ Cometæ diametro.] *On the true diameter of the comet.*

To determine the diameter correctly in miles or in semidiameters of the Earth, certain data are required: first, namely, the size of the diameter of the comet as seen; second, its distance from the Earth; and third, the shape of the head. The first is established from observation: the diameter of the phenomenon at least equalled the Moon's disc, if it did not exceed it. But although some astronomers suppose the diameter of the Moon at apogee to be 34′, 35′, indeed 36′, let us nevertheless set the comet's diameter on this occasion at no more than 30′, namely for 20 December; for we prefer to be seen to err by defect rather than by excess. Nor, indeed, does it matter much to neglect one minute or another, or to concede it freely to our opponents, since its size will nonetheless grow to an immense amount.

2. The distance of the comet from the Earth for 20 December, however, was derived and shown to have been 110 semidiameters of the Earth [S. T.], one semidiameter of the Earth containing 860 German miles.

[Margin: Diſtantia Cometæ à Terrâ.] *The comet's distance from the Earth.*

3. The shape of the head, as far as could be grasped with the naked eye, appeared almost round, as does that of nearly all comets. Not that comets really always show an absolutely perfect roundness; they are only seen in roughly the same form. For I am fully convinced that if these phenomena were looked at close at hand, they would not present a figure of a circle perfect in every respect, as will become clear from what is to be said below. However that may be, let us suppose, following the common opinion, that the comet was quite round, and on this hypothesis let us now set about the calculation.

[Margin: FiguraCapitis.] *The shape of the head.*

In the diagram that follows, let B D be the comet's apparent diameter of 30 minutes, and A C the comet's distance from the Earth, 110 S. T., that is, 94600 German miles; the triangle to be solved is A C D, right-angled at C. And in this very acute triangle let the two sides A C and A D be equal, since as a result nothing is either taken from this business or added to it. Now if from the given angle C A D, namely the semidiameter of the phenomenon, 15′, and the distance A C, you compute C D: as the whole sine is to the tangent of the angle, so A C, the distance from the Earth, 94600 German miles, will give 412 57/125 miles, namely the semidiameter of the phenomenon; its double gives the whole diameter, 825 miles. The same results from the logarithmic calculation.

[Margin: Methodus calculi, pro inveniendâ Cometæ diametro in mill.] *Method of calculation for finding the comet's diameter in miles.*

Mesolog.	15′ 0″	543452	
Logar.	100 S. T.	950986 *Add.*	
Log. of the semid. sought		994438	
Log. of one semid. of the Earth		921034 *S.*	
Logarith.		73404	48/100 | 00/00 | 12/25 semid. of the Earth, which are to be converted into miles.
Logarith.	86010	15082 *A.*	
Logarith.		88486 — 412 7/10	miles; therefore the whole diam. 825 2/5 miles.

536

But, you will say, if we weigh this business a little more accurately, it seems that we have not yet arrived at a perfect measure of the true diameter. For since A C and A D are not parallel, but drawn as if from a centre to different

[536] set unruled in the page's own columns, with a short rule under the second, fourth and sixth figures. The label of the second line prints 100 S. T., where the text gives the distance as 110 S. T.; the figures stand as printed.

points of the diameter of another circle, they cannot both be equal; rather A C, passing through the centre, will necessarily always be longer than the tangent A F. For where a tangent touches the circumference, there the semidiameter of the circle meets the tangent at a right angle: according to Theor. 15, prop. 16, and Theor. 16, prop. 18; likewise the Corollary to Theor. 15, prop. 16, of Euclid III. Therefore in the triangle A F C, A F, as the base, is altogether smaller than A C, the hypotenuse. And for that reason the calculation must be undertaken by another route, although this will detract little from the business; nor does it matter much whether it is some miles larger or

[Margin: Alia fecurior ratio diametrum inveſtigandi.] *Another, safer way of investigating the diameter.*

smaller, that diameter. Nevertheless, let us see no less diligently whether any difference can be noted. When the calculation has been set up in this way and properly carried through, you will find that A F comes to 94,599 miles, so that it is smaller by scarcely one mile than the distance A C from the Earth assumed earlier. From this A F and the angle C A F, 15′, the true semid. F C comes out as 412 13,791/25000; and so the whole diameter is about 825, as above, exceeding the earlier one by scarcely 3/25 of one mile — which certainly comes into no consideration here.

With the true diameter thus found, the circumference of the whole body is also derived with very little trouble. For according to the Archimedean proportion and demonstration — as 7 to 22, or if you prefer, as 100 to 314, or as 1600 to 5041, that is, of the diameter to the circumference — the whole circumference of the comet comes out at 2593 41/175. If half of this, neglecting the fraction [refractione], is multiplied by the semidiameter of the comet found above, 412, the product, 535,174, will be the area of the great circle of the cometary body, namely in square miles.

[Margin: Circumferentia corporis Cometici.] *The circumference of the cometary body.*

Diagram. An engraved plate in a plain rectangular frame, set at the left of the measure beside the narrow column of text that follows, holding three drawings side by side and no caption. On the left, a circle with centre C: a vertical line runs from the top of the circle through C to a point A at the foot of the plate; a horizontal line B D crosses the circle through C; lines run from C to the points E and F on the circle, below B and D; from E and F two long lines descend and converge on A. In the middle, a smaller circle with centre H: a horizontal line d e crosses it through H; lines run from H to f and g on the circle, and from f and g two lines converge on a point c below; two long lines descend from near d and e and touch a large circle at the foot, which carries A at its centre. On the right, a circle with centre H and the same letters d, e, f, g and c as the middle drawing; two long lines descend and enclose a small circle at the foot, which carries B. All the letters printed on the plate were read; there are no others.

- B, C, D, E, F (left drawing): the left and right ends of the horizontal line (B, D), the centre (C), and the points on the circle below them (E, F)
- A (left drawing, foot): the point where the two long lines meet
- d, H, e, f, g, c (middle drawing): the ends of the horizontal line (d, e), the centre (H), the points on the circle (f, g), the point below where two lines meet (c)
- A (middle drawing, foot): inside the large circle
- d, H, e, f, g, c (right drawing): as in the middle drawing
- B (right drawing, foot): inside the small circle
- Autor ſculps. (lower right, engraved script): "The author engraved it."

[Margin: Area totius corporis Cometici in mill.Cubicis.] *The area of the whole cometary body in cubic miles.*

Next, the area of the whole surface, and likewise the bulk, can also be determined without difficulty, provided the body is supposed to be completely round, like a sphere — as most have held until now concerning all the planets and comets. Indeed, the Peripatetic school works hard [alloborat] to establish that this is entirely so, although we think quite otherwise, as we shall shortly prove more fully. But granting that the comet has a spherical shape, the area of the whole convex surface — if, that is, the whole area of the circle is multiplied by four, in the manner customary among geometers — comes out at 2,140,696; a sixth part of this, multiplied by the diameter 825, gives the area of the whole cometary body in cubic miles: 294,345,150. You see, then, that the comet displayed a rare and remarkable size. For whoever had set out to go round it, even supposing he covered 10 miles every day, would nonetheless use up 259 days and 4 hours, or 37 weeks, in completing that whole journey.

[Margin: Quanto dierum intervallo in ſuperficie globi Cometici, ſub circulo maximo, iter conficeretur.] *In what interval of days a journey would be completed on the surface of the cometary globe, along a great circle.*

And yet, however astonishing the size of the comet was by this reckoning so set up, in reality it was nonetheless somewhat larger still, if you look into the matter more deeply; and indeed for two different reasons. 1. It is certain that no spherical or round body which has a definite thickness and which exceeds our pupil in size can be seen under its greatest circle, but always, in proportion to the size of that visible body, only under some smaller one — granting even that the illuminated body is somewhat smaller, or

[Margin: Cometæ ſemper majores ſunt quàm apparent,& unde ?] *Comets are always larger than they appear; and from what cause?*

equal to the illuminating body. 2. The same thing happens even though the illuminating body is larger than the illuminated body, because the illuminating body then illuminates less than half of the illuminated body. And therefore, from these two concurring causes, comets are necessarily always larger in reality than they appear: as is demonstrated from the preceding diagram, but better still from those added here.

Let A be the larger illuminating body, B the smaller, H the illuminated body, and c our eye. The rays drawn from the larger illuminating body A to the body H do touch that same body H at *d* and *e*, a little beyond the half; but the tangents *c f* and *c g*, coming from the eye, take in only a smaller part, the part lying between *f* and *g*; and so no more is seen. In the same way it is clear from the other diagram that not only does the smaller illuminating body illuminate less than half of the illuminated body, but the visual rays also subtend at *f* and *g* a still smaller part of that spherical body: which was to be proved.

But so that we do not linger too long over these subtleties — whether, that is, the comet was a little larger or rather smaller — let us go further and explore what proportion held between the Sun, the Moon and the comet, in respect both of diameter and of solidity. Before that can be done, however, the size of the diameter of the Sun, of the Moon and of the Earth must be known. As for the diameter of the Moon, it contains 495 miles. The diameter of the Sun, according to Kepler, is 22 semidiameters of the Earth, that is, 18,922 German miles; so that the ratio of the Earth to the Moon is as 7 to 2, and of the Earth to the Sun as 1 to 11. But if you want these figures still more exactly, and indeed according to the views of various leading astronomers, here is the little table that follows, from which you will learn all these things with almost no trouble according to Ptolemy, Copernicus, Tycho, Kepler, Boulliau and Riccioli.

[Margin: Proportio diametrorum Solis, Lunæ & Terræ; juxta diverſos autores.] *The ratio of the diameters of the Sun, the Moon and the Earth, according to various authors.*

537

Now, further, we must investigate how these bodies, namely the Sun, the Moon and the Earth, stood in relation to our comet in respect of diameter and of solidity. It is evident that the diameter of the Earth amounts to 1720 miles, that of the Moon to 495, and that of the comet to 825; from this it follows that the diameter of the comet has to the diameter of the Moon the ratio of 52 to 25 7/10; to the diameter of the Earth, that of 52 to 100; and to that of the Sun, that of 52 to 1500. That is, the diameter of the comet exceeds the diameter of the Moon 1 22/33 times; that of the Earth, 2 2/33; and the diameter of the Sun, nearly 23 times. If you consider solidity, the comet stands to the Moon as roughly 9 to 1; to the Earth as 9 to 59; and to the Sun as 9 to 204,671. So it appears from this that in respect of its body the comet was nine times larger than the Moon, but 6 5/9 times smaller than the Earth and 22,741 times smaller than the Sun. But I would have you note that this proportion held between those bodies on December 20, when the comet was first beginning to appear to us. So that you may grasp these proportions all the more clearly, however, I have set them out in tables, and indeed according to the various authors, as above. The first shows the ratio of the Moon, the second that of the Earth to the other bodies, the diameter of the Earth being taken, that is, as 1000 parts.

[Margin: Quantitas diametrorum Solis,Lunæ,Terræ &Cometæ.] *The size of the diameters of the Sun, the Moon, the Earth and the comet.*

[Margin: Cometa quoties Lunâ major; Terrâ verò & Sole minor extiterit ?] *How many times was the comet larger than the Moon, but smaller than the Earth and the Sun?*

537 the table runs across the full measure under a ruled title band. The Sun sign and the Moon sign each stand alone in a ruled band across the table, heading the two blocks of six rows; here each is set in the first cell of its own row. The column headings are set in two tiers, the quantity above and its unit below, the unit row given here in italics as printed; the first column carries only its lower heading, "Nomina Autorum.", rendered in the header. The apparent diameters are printed as two figures under "Mi.Se.", minutes and seconds. In the last column a point stands after the sixth figure from the right, and in the Riccioli row of the Sun block and the Boulliau row of the Moon block a space stands in its place. A rule divides the first three rows of each block from the last three. The authors' names are printed in Latin, abbreviated in the Sun block (Ptolem., Copernic., Tych. Brah.) and in full in the Moon block.

Table showing the proportion of the diameters and solidities of the Sun, the Moon, the comet and the Earth according to the various hypotheses of the practitioners [Tabella exhibens Proportionem Diametrorum & ſoliditatum Solis, Lunæ, Cometæ & Terræ ex diverſis artificum hypotheſibus.]

538

On each of the following days, however (since the apparent diameter of the comet decreased from day to day as its distance from the Earth grew again), both its true diameter and its proportion to the Moon, the Earth and the Sun will show themselves quite otherwise. But whether the apparent diameter of the phenomenon was really increased, or rather diminished on account of the distance, must be weighed and investigated somewhat more exactly. This will not only bring much pleasure, but will also be of great use in resolving extremely difficult questions, especially when we come to speak of the origin and end of comets.

538 the table stands in one frame across the full measure and into the left margin. Under the title, two blocks stand side by side with an empty space between them: the left block holds the authors' names and six columns; the right block, under its own group heading, holds the authors' names again, in the genitive (Ptolemæi, Copernici, Tychonis, Keppleri, Bullialdi, Riccioli), headed "Ex ſententiâ", and three columns. The three group headings, each spanning three columns, are given here in the second row. A double vertical rule divides the diameters from the bodies in the left block. A rule divides the first three rows from the last three. The last column carries a figure in the first row only. *ferè* and *fer.* ("nearly") are printed in italics beside the figures.

[Margin: An diameter Cometæ apparens reverà; an verò ratione intervalli ſolummodò indies decreverit ?] *Whether the apparent diameter of the comet decreased from day to day in reality, or only on account of the distance?*

But so as not to keep the kind reader's mind in suspense with a long calculation (one already made abundantly clear from what precedes, and which here must proceed along a similar route, with only the comet's diameter and distance varied for each day), I shall therefore at once set before your eyes, for each day, in particular tables, not only the proportion of the comet's size, according to its various distances from the Earth, to the size of the Earth, and likewise of the Sun and the Moon, from the Keplerian hypotheses; but also how, as the apparent diameter and the distance varied, both the true diameter, the area of the circumference of the circle and of the convex surface, and the solidity of the globe itself turned out differently from day to day.

[Margin: Singulis diebus diverſam magnitudinem poſſedit.] *It had a different size on each day.*

The proportion of the comet's size, according to its various distances from the Earth, to the size of the Earth, and likewise of the Sun and the Moon, from the Keplerian hypotheses [Proportio Magnitudinis Cometæ juxta varias ejus à Terrâ Diſtantias, Ad Quantitatem Terræ,itemq́; Solis & Lunæ ex Hypotheſibus-Kepplerianis.]

539 the table stands under its two-line title in a ruled frame, a double vertical rule dividing the first five columns from the last two. In the first row the dates 20 and 21 are set small, one above the other, in the height of a single row, and the distance column holds 110 above 110, joined by a brace; each other column of that row holds a single figure. The rows stand in blocks of three divided by rules, the month named in the first row of each block. In the last row the numerator of the fraction in the sixth column is not settled between 3 and 2.

540

From these tables it is clearly seen that, although from day to day the comet was more and more notably diminished as to its apparent diameter, from 30′ to nearly 5′, and also became much fainter and duller from day to day, so that around its last appearance it almost escaped sight, nevertheless from December 23 it grew as to its true diameter, circumference and solidity, and increased wonderfully every day: whereas, indeed according to your view, exactly the opposite ought to have happened. For its apparent diameter, found on December 23 to be only 800 miles, already exceeded the size of the Earth's diameter on the 28th of the same month; on January 30 it was larger than Jupiter; and on January 4 it already surpassed Saturn in size. Finally, toward the end of its appearance, it came nearly to the size of the Sun. Rightly, then, is this phenomenon held to be a body of unusual and astonishing size, since

[540] the second table follows the first inside the same frame, under its title set in a ruled band across the full width. The column headings are set in two tiers, the quantity above and its unit below, the unit row given here in italics as printed: semidiameters of the Earth; minutes and seconds; German miles; square German miles; square miles; cubic German miles. The first column has no heading. The apparent diameters are printed as two figures under "Min." and "Sec.". In the first row the dates 20 and 21, and the distances 110 and 110, are set small, one above the other, in the height of a single row, the distances joined by a brace. The rows stand in blocks of three divided by rules.

toward its departure it nearly equalled the Sun itself, even though the Sun is given as 3462 times larger than the Earth.

[Margin: Cometa ut ut apparenter, quoad diametrum decrevit, reverà tamen mole crevit.] *Although the comet decreased in appearance as to its diameter, it nevertheless really grew in bulk.*

[Margin: Cometa circa exitum, Solis ferè magnitudinem æquavit, corpus ſi ſit ſphæricum.] *Toward its departure the comet nearly equalled the size of the Sun, if its body is spherical.*

[Margin: Quantò Sol Terrâ major exiſtat.] *By how much the Sun is larger than the Earth.*

No one, indeed, will be able to deny that everything — both the true diameter and what is attached to it — has been duly deduced from the comet's correctly found true distance and its observed apparent diameter, and so that on that foundation the comet was by no means smaller. Yet it still in no way follows from this that the solidity of that cometary body necessarily nearly equalled the solidity of the Sun. For the reason this phenomenon reached that immense quantity is that its body, according to the popular opinion, long ago proclaimed by the Peripatetics, is taken to be an entirely spherical body.

[Margin: Cometa corpus Solare reverà non æquavit.] *The comet did not in reality equal the body of the Sun.*

But whatever the case, those who hold this view aim very wide of the mark. For if we keep to sound reasons, and to our own observations and those of others, it will be evident that the bodies of comets are almost never wholly spherical, but only, as to the head, round and disc-shaped bodies, which nevertheless, by reason of their matter and the constitution of the body, have a certain thickness, spread out or extended like the spots and faculae of the Sun; so that these phenomena by no means consist of one solid body, or nucleus, compacted into a sphere, as indeed happens in the other planets, but consist of manifold and various opaque nuclei and bodies, loosely adhering to one another, with another matter, rarer and subtler, lying between them here and there and giving the rays of the Sun a free passage.

[Margin: Corpora Cometica minimè ſunt ſphærica; ſed diſciformia.] *The bodies of comets are by no means spherical, but disc-shaped.*

[Margin: Cometæ ex diverſis nucleis atq; corporibus conſtant.] *Comets consist of various nuclei and bodies.*

I am led wholly to this view both by compelling reasons and by some examples of comets, especially since I clearly detected this very thing with my own eyes in the recent comet. For from our observation made on December 27 with the help of the telescope, you have understood properly and without any doubt that I noticed in the cometary head itself various small bodies, like very tiny twinkling little stars; some of these were extremely small, barely striking the eyes, and some also a little larger, toward the east; in the west, however, a certain winding, rarer light; just as if it were a heap of very tiny small bodies

that could in no way be distinguished from one another: as is clear from the earlier drawing of that observation inserted on p. 327.

[Margin: Id quod exemplis comprobatur.] *This is confirmed by examples.*

And so it is clear that the body of the comet was in no way spherical, nor continuous and dense, consisting, that is, of a single body or nucleus; but rather that it was compounded of innumerable and most diverse bodies, some more opaque and some rarer, now closely cohering with one another, now with certain small spaces between them, as can be seen in the nebulous little stars and in the Milky Way. Hence it happens that when this cometary matter first begins to condense, the comet's head is then actually far larger in diameter than when it has already reached maturity, when the matter is more compact and the larger nuclei, as it were, associate with one another. The reason is that at this stage, because of the greater compression of the matter, its diameter cannot be so large. But when the head begins to thin out again and the small bodies to spread apart, then the matter, dispersing itself more and more, is once again extended more widely, and the head actually grows in diameter.

[Margin: Cometa qualè ſit corpus ex mente Autoris.] *What kind of body a comet is, in the author's view.*

[Margin: Quando Cometæ caput ſit maximum.] *When the head of a comet is largest.*

From this hypothesis it is proved that, since the small bodies of which the comet's head is composed continually change their position and shapes, and are little by little drawn further and further apart, that cometary head too must necessarily always shine more dully, more palely and with a gloomier colour, as it is in reality rarer, than when it is denser and packed with larger bodies. For the denser and more opaque it is, and the larger, more solid and more compressed its nuclei, the more clearly and strongly it reflects the light and rays of the Sun; and consequently comets then also appear more splendid and vivid than when the matter rarefies again and the nuclei separate and scatter.

[Margin: Quinam Cometæ ſint pallidi & obſcuri; rursùs quinam clariſſimi & ſplendidiſſimi.] *Which comets are pale and dim; and, in turn, which are the brightest and most splendid.*

Resting on this solid foundation, you will be able to explain and save successfully any of the phenomena of all comets: namely, where the various appearances of the tails and their various sizes come from; why very large comets, in respect of the head, sometimes appear dim and weak, and small ones, on the other hand, sometimes appear most splendid and brightest; how it happens that those nearer the Earth are smaller, while those farther away are in turn actually larger, although to the naked eye they are perceived as smaller; and very many other paradoxes of this kind. It is enough to have touched on them here in passing, and we reserve them for their own place and time, where we have proposed to treat all of them deliberately.

[Margin: Ex Autoris hypotheſi ſingula Cometar. phanomena integra ſunt.] [recte: phænomena] *On the author's hypothesis, each of the phenomena of comets is intact.*

These things that we have just said, namely that the small bodies and nuclei of comets wonderfully change their place, shape and size, and keep various distances among themselves, ought properly to be demonstrated by examples as well. But, to confess the truth, this cannot be done from our observations of the comet, however much I should wish it: for, hindered by other observations, I examined the comet with the telescope only twice, and by no means on each day, namely on December 27 and lastly on January 10, when the more solid nuclei were already quite extinguished. Nevertheless, reason suggests that on the 20th the comet consisted, if not of larger nuclei, at least of very many lying quite close to one another, with more solid matter scattered among them, since at that time it was most conspicuous; but afterwards, as the matter gradually rarefied and the nuclei were drawn apart and scattered, it necessarily appeared paler and dimmer.

[Margin: Corpuſcula ex quibus Caput Cometicum conſtat, perpetuò variantur, mutantur, locoq́; diverſimodè moventur.] *The small bodies of which the cometary head consists continually vary and change, and are moved from their place in diverse ways.*

That this happened in this way and not otherwise, we learn clearly from the most excellent observations that Father Cysat made of the comet with the telescope. For in the comet of the year 1618 he very distinctly and many times detected almost the same thing that we reached above about our own comet, only by conjecture; just as I also do not hesitate to affirm that the same happened in the other comets too, provided only that it had been duly observed by our predecessors. Indeed, I have no doubt at all that all those that will ever shine hereafter will demonstrate the same. For I would have you know that exactly the same thing occurred also in the comet observed by me in the year 1661. Since, God willing, I have proposed to describe it toward the end in a separate Book, I do not wish to say more about it on this occasion: you will see there that, as in this matter, so also to all the things that we have stated about comets in general, that comet added great strength.

[Margin: Id quod obſervationibus Cyſati evidenter probatur.] *This is plainly proved by Cysat's observations.*

But before we set out here Cysat's observation itself of the comet of the year 1618, with its genuine drawing, the observations of certain other most distinguished men on the same phenomenon must be given first, so that the matter may become all the clearer and more certain.

1. The excellent P. Crüger, once my teacher, always to be honoured with the best remembrance, says in his *Uranodromus Cometicus*, p. 2, that on December 1 he observed the comet truly large and fiery, with a tail of the same kind, about 9°; but on December 2 much smaller in size and duller in light and colour; on December 8 it showed a head that was by

no means ruddy, but much larger, and a tail extending to nearly 60°; on December 15 the tail appeared scarcely a little smaller, but the comet had decreased somewhat in its head. The same was observed in the following days, so that on the 29th it appeared greatly diminished.

[Margin: Crügeri obſervatio Cometæ anni 1618.] *Crüger's observation of the comet of 1618.*

2. The most experienced D. Isaacus Habrechtus [Isaac Habrecht], formerly physician to the Most Illustrious Count of Hanau [Hanaw], set out this same comet, observed at Strasbourg [Argentorati], in a certain small work, pp. 21 and 22, as follows: The phenomenon was round in its head and furnished with a tail; on November 21 it was detected at no mean size, and to a keen-sighted observer it appeared surrounded as if by a triple circle. The outermost flickered with a vibrating, twinkling and inconstant light, the middle one with a gentler light, to be sure, but a much more vivid one; but the inner one, the third of all, was the most splendid and brightest, so that it could be compared to nothing rather than to the splendour and brilliance of molten gold standing in the fiercest fire, etc. He adds that on the same day, in the morning, it gave out such splendour that it lit up the Earth with its light more than Venus at perigee, though its light was gradually decreasing. But the colour at first was to some extent ruddy, yet becoming whiter and rather pale; at the last it was very pale and very dim, like the Milky Way, etc.

[Margin: Cometam miram habuiſſe faciem Habrechtus teſtatur.] *Habrecht testifies that the comet had a wonderful appearance.*

3. But Cysat, more exquisitely than anyone so far, with a more accurate telescope noted that comet of the year 1618, as regards its head, colour and light as well as its manifold variation and the constitution of its body, and drew it graphically. All of this deserves to be well noted in this place, and even to be touched on somewhat more fully, since no one ever before carried out such extremely exquisite observations; and indeed, without any doubt, no small benefit flows from them to the world of learning in respect of this subject of comets, and the earlier obser-

[Margin: Cyſatus omnium primus Teleſcopio Cometam contemplatus eſt.] *Cysat was the first of all to view a comet with the telescope.*

vations are greatly illuminated and corroborated. But to return to Cysat's observation itself: On December 1 and 4 (he says) we examined the comet with diligent and prolonged inspection through the optical tube, and indeed through a pair of them, one about 6 feet long, the other 9 or 10. The star of the comet, or that more condensed light immersed in the comet's head, which we may from now on call the light, the nucleus or the core of the comet's head — this nucleus, I say, of the comet's luminous head appeared round in shape, with a continuous and compacted light, although by no means bright or brilliant. Its diameter was indeed larger than that of any fixed star of the first magnitude, if that star too is viewed through the tube, but much smaller than the diameter

of Jupiter appeared on the same days, so that at most it could have taken up two thirds of the Jovian diameter.

[Margin: Exquiſitiſsima Cometæ 1618 obſervatio à Cyſato habita.] *A most exquisite observation of the comet of 1618, made by Cysat.*

Further, this nucleus of the comet's luminous head, of a dense but leaden and dark light, had all around it a rarer and paler light, in a border [limbus] nearly twice as broad as the diameter of the nucleus itself. The phenomenon is very like the one the Moon presents when it shines through little clouds or vapours, or thin clouds, with a pale border poured around it, itself pale as well; nor is it very unlike that nebulous star which is seen with the tube above the Girdle of Andromeda, toward the north, except that this star is far dimmer than the comet. And although a certain third radiance [jubar], of far more diluted and dimmer light, also surrounded that nebulous corona which encircled the nucleus, yet because that light was not denser than the light of the comet, and indeed seemed to be the comet itself flowing out, we were unwilling to count it as part of the comet's head. The comet's head therefore consisted of a dense core or nucleus and a crowning border, broader indeed, but of much rarer light: and the diameter of the nucleus was about 2′, the breadth of the border 3′, the whole diameter of the head about 8′.

[Margin: Caput iſtius Cometæ denſo conſtabat nucleo.] *The head of this comet consisted of a dense nucleus.*

December 8. Not only the whole head of the comet (that is, the nucleus together with the radiance poured around it), but also the nucleus on its own appeared twice as large as Arcturus in diameter, 3′ or 4′ (whereas on the first day it had been far smaller); and it was no longer round, but split into three or four globules of irregular shape, cohering with one another, such as the companions of Saturn usually appear.

[Margin: Nucleus Cometæ in plures abiit die 8 Decembr.] *The comet's nucleus broke up into several [parts] on December 8.*

December 17. In place of that nucleus, lately compacted, there now appeared some extremely small little stars, with a very dull light poured around and among them, glittering forth as if out of a mist or a white cloud; and this was seen much more clearly and distinctly on the following day, the 18th.

December 20. The core or nucleus, which on the first day had appeared as an almost solid and round light, appeared more plainly dissolved into many little stars, so that it was now a cluster of a great many very small little stars, of which three were seen more constantly and distinctly than the rest, and the largest of them was like a star of about the 5th magnitude. Besides this, outside that cluster of little stars, a little star also shone out in the radiance poured around it, which at first was thought to belong to the rest of the cluster; but after an hour and a half it proved to be one of the fixed stars, when it had already moved 6′ away outside the radiance. This little star, too, was far smaller than the smallest companion of Jupiter. Finally, the diameter of this nucleus, or now of the globe of stars, was 5′ or 6′, certainly notably larger than on December 1.

[Margin: Caput Cometæ apparuit, ac ſi esſet multarum Stellularum congeries.] *The comet's head appeared as if it were a cluster of many little stars.*

December 24. Both the nucleus, or globe and cluster of little stars, and the radiance itself poured around it occupied a far larger space than before, but with a much thinner and rarer light. Of the three little stars lately distinguished, now only one con-

[Margin: Caput indies crevit quoad diſcum, quoad lumen verò & ſplendorem decrevit.] *The head grew day by day in its disc, but decreased in light and splendour.*

stantly appeared; the others were indeed very many, but could not be counted distinctly, because, although they were seen twinkling surely and often, yet they did not meet the eye continuously and steadily all together, but intermittently, one after another, as if by leaps, in just the way that the smallest fixed stars are usually seen even with the naked eye in a very clear sky. Finally, the individual [little stars] were also today far more scattered from one another than on the previous days, so that the diameter of the nucleus was at least 6′, the breadth of the surrounding border 5′, and the whole diameter of the head about 16′. And this was the last day on which it could be observed through the tube. What has been said is represented, as far as it can be, in the diagrams below.

Diagram. An engraved figure of four round comet heads, two above and two below, each a disc fringed with fine radiating strokes. Upper left: a small round nucleus ringed by a dark dotted circle. Upper right: a nucleus broken into a few dark irregular patches inside a lighter round area. Lower left: a larger, irregular light area strewn with small star-shaped points. Lower right: a still larger light area strewn with more star-shaped points. Each head is dated by an engraved label above it; the engraver's note stands below the lower right head. No letters stand on the heads themselves.

- Above the upper left head: Decembr. 1. — December 1
- Above the upper right head: Decemb. 8. — December 8
- Above the lower left head: Decemb 17.18.20. — December 17, 18, 20
- Above the lower right head: Decembr. 24. — December 24
- Below the lower right head: Autor ſculpsit. — The author engraved [it].

[Margin: Genuina facies Cometæ anni 1618.] *The true appearance of the comet of 1618.*

It should further be noted that from the first day of December to the 24th the comet's head actually always grew in a certain proportion as regards its extent, whether you look at the nucleus or at the radiance poured around it; but as regards the density and clarity of its light it always became diminished, and more diluted and rarer. Thus through the tube the comet's head appeared smallest on the first day and largest on December 24. Exactly the opposite happened to unaided sight: to it the comet's head appeared largest on December 1 and far smaller on the 24th, namely because of the dispersal of the little stars and the diminution of the light.

[Margin: Idem deprehendit Scheinerus Æniponti.] *Scheiner found the same at Innsbruck.*

Lastly, the author adds that he observed all these things, together with other learned men, with the greatest diligence and good faith, so that he often spent half an hour, and sometimes a whole [hour], entirely without a break, in inspecting and examining this phenomenon. Likewise Christophorus Scheinerus [Christoph Scheiner], most practised in observations, observed this comet at Innsbruck [Æniponti] with an altogether similar appearance: on this you may read, if you please, Book IV, Part II, Chapter XIII, p. 612 of the *Rosa Ursina*.

[Margin: In Com. 1618. Capitis nuclei in plures disfecti fuerunt, teſte Wendelino.] *In the comet of 1618 the nuclei of the head were cut apart into several, as Wendelen witnesses.*

Moreover, Govaert Wendelen likewise attests this very thing — namely that the comet's head was composed of most diverse small bodies exercising their own particular motion, which afterwards were resolved and, as it were, cut apart into very many other smaller ones — in his *Teratologia Cometica* Luminarcani, p. 21: For the head of the comet itself, he says, when I first explored it with the telescope on November 29, I found to be like three or four bright coals of a huge hearth, kindled with a strong fire. I saw, I say, the comet as if a triple globe: and indeed I noticed that these three coals changed their position somewhat in my presence, as if there were someone stirring the hearth; and on the following days more coals were seen by me, just as our coals, once kindled, leap apart into several pieces.

From these observations, and from those of all the others who watched that comet at that time, we clearly gather that the comet's head and tail appeared to the naked eye to decrease from day to day, both in size and in light; and that about the time of its last appearance it became so thin and faint, like some nebulous star or a small part of the Milky Way: just as was noticed in that comet which shone forth in the reign of Attalus, of which Seneca [says]: that, being moderate at the start, it suddenly raised itself up and spread out, and equalled the Galaxy.

[Margin: Corpus Cometicum ex multis componitur corporibus.] *The body of a comet is composed of many bodies.*

With more accurate tubes, however, they found, first, that the comet of 1618 was by no means compacted and fused together out of one solid body, still less a spherical one, but out of many most diverse bodies and irregular nuclei, which continually changed their size and position; so that those nuclei constantly exercised a particular motion of their own, as much of alteration as of place, from which afterwards a great change in its appearance arose.

Second: they noticed that the comet appeared very bright at the beginning, but afterwards successively paler and darker.

[Margin: Cometa 1618 initiò ex uno ſolidiori conſtabat nucleo.] *The comet of 1618 at first consisted of one more solid nucleus.*

Third: that the comet at first consisted of a single, more solid nucleus, which a more diluted rim surrounded. That on December 8 this nucleus was divided

into three [parts] of irregular shape; which then, namely on the 17th and 18th, degenerated into various extremely small, as it were, little stars; and on the 24th, dissolving themselves into a great many far smaller ones.

[Margin: Quâ ratione caput Cometæ illius creverit.] *In what way the head of that comet grew.*

Fourth: that the middle or nucleus of the comet, together with the very radiance poured around it, always grew as regards the size of its disc, but as regards its light and clarity, and its density, always decreased: so that on December 1, about its beginning, the nucleus was only 2′ in diameter; on the 8th, 3′ or 4′; on the 20th, 5′ or 6′; and on the 24th, at least 6′. But the whole diameter of the head appeared, not only with the help of the tubes but also of instruments, [as] 8′ on December 1; 10′ on December 8; 13′ on the 17th; 14′ on the 20th; and 16′ on December 24.

[Margin: Cometa 1618 continuò à terrâ magis magisq; elongatus eſt.] *The comet of 1618 continually moved farther and farther away from the Earth.*

Moreover, according to each and every observer, it is most certain that the comet was nearer the Earth about the time of its first rising, and afterwards withdrew farther from the Earth day by day. But I think I have now said enough both about the observations themselves of the comet of 1618 and about the points most worth noting in them. Let us now also see whether all those appearances, and whatever phenomena commonly occur in comets, can be saved on the supposition that comets consist of extremely small bodies of diverse kinds.

[Margin: Philoſopho incumbit ſententiam ſuam in ſenſuum evidentiam ſempe referre.] *It is the philosopher's duty always to refer his opinion to the evidence of the senses.*

For it befits a philosopher above all to refer his doctrines always to the evidence of the senses: just as Aristotle himself, the coryphaeus of philosophers [Philoſophorum Coriphæus], never inculcates anything more than that, in explaining the nature of each thing, the appearances of things must be saved. Likewise, in the *Univers. Philosoph.*, chapter VIII, pages 117 and 174, Franciscus Baco de Verulamio [Francis Bacon], a man indeed of the most profound learning, urges *that the decrees of philosophy should be such as are entirely explicable upon the phenomena of astronomy*.

[Margin: Ex Autoris hypotheſi omnes apparentiæ egregiè ſalvantur.] *On the author's hypothesis all the appearances are excellently saved.*

Far be it from us too, therefore, to lay down anything in this most subtle business of comets that would seem to conflict outright with the phenomena. For my part, unless my own [ideas] please me too much, I think that all these matters, whatever pertains to comets, can hardly be better explained and derived from any other hypothesis: as will soon become clearly evident from the questions to be raised.

[Margin: Cur Com. 1618 principiò ſplendidior extiterit ?] *Why was the comet of 1618 more splendid at the beginning?*

1. So it is asked: from what cause did the comet of the year 1618 appear much clearer and brighter at the beginning than at the end? Answer: because it consisted of one single nucleus or body. Since this nucleus was at that time of remarkable size and of rare solidity, it consequently reflected the rays of the Sun to us more strongly and more vividly (for I hold that comets enjoy no light of their own, but only borrowed light) than if it had been dissolved into smaller and rarer nuclei, with little spaces lying abundantly between them and very thin matter scattered among them. For a more solid body is far better suited to reflecting rays than a rarer one, as optics teaches.

[Margin: Cur idem Cometa die 8 Decemb. pallidior fuerit ?] *Why was the same comet paler on December 8?*

2. It is asked why on December 8 it was already somewhat paler and darker. Answer: because at that time it had already split into three smaller nuclei. And for that reason on the 17th it was seen still duller, namely because it had been dispersed into many more nuclei, or little stars; indeed, on the 24th it was found extremely pale and extremely dark, because the comet had been reduced into a great many extremely small, rarer corpuscles and more diluted matter.

[Margin: Cometæ quò paucioribus & ſolidioribꝰ conſtant nucleis, eò lucidiores ſunt ?] *The fewer and more solid the nuclei comets consist of, the brighter they are?*

From this, therefore, we rightly conclude that the more splendid and brilliant comets are, the fewer but larger and more compact are the nuclei they consist of; whereas the paler and darker they appear, the more numerous, but smaller and rarer, are the nuclei and corpuscles they are composed of, standing farther apart from one another, with more diluted matter mixed among them.

[Margin: Cometa 1652, cur ſubobſcuri pallidiq́; fuerit coloris ?] *The comet of 1652: why was it of a darkish and pale colour?*

For this reason the comet of the year 1652 never appeared as splendid and bright as that other one of the year 1618, as it was seen on December 1: because this one [of 1618] consisted of larger nuclei — indeed, around its first appearance, understand, of one single nucleus — while that one [of 1652] consisted only of many extremely small corpuscles, and these, moreover, quite rare, with very abundant, more diluted matter lying between them.

[Margin: Ex lumine & coloribus motus nucleorum, ex quibus caput aliàs conſtat haud malè cognoſcitur.] *From the light and the colours, the motion of the nuclei of which the head in any case consists is recognised quite well.*

From this, too, it is not badly inferred (in my opinion at least) that our comet was continually of a pale colour, gradually fading: namely because its nuclei continually moved farther and farther away from one another, and were separated by a certain very slow proper motion of those nuclei. On the contrary, since in the comet of the year 1618 the nuclei changed very rapidly in position, shape and number, and so displayed a very swift motion, that sudden change of

colours and light arose from this. For whatever comet, according to this given hypothesis, suddenly varies its colours and light, its nuclei, of which the head is composed, are endowed with a very swift motion. Conversely, those comets that change their colours gradually consist of such bodies as enjoy a very slow motion; and the comet of the year 1652 is rightly counted among their number. This is clear from Wendelen's observation, made on December 21, and from ours, made on the 27th of the same month: namely, that the motion of the nuclei relative to one another was very slow, since they varied their position and shape very slowly.

[Margin: Quo compactior materia, eò lucidiores ſunt Cometæ.] *The more compact the matter, the brighter comets are.*

It follows, next, that there can also be some comets which, though their head is smaller, are nevertheless most splendid and most bright; and conversely others, with a larger body indeed, but very pale and very dark. The smaller ones [are such] when they have grown together out of one, namely, large and dense nucleus; but the larger ones, when they consist of many nuclei, very small and rather rare corpuscles. But if some comet, large in its head and most splendid, should shine forth, like the one before the war against the Achaeans, which had risen: I fully believe that such a [comet] consisted of [nuclei] at once large and at once extremely solid, glued closely to one another as it were, and of extremely dense matter; in accordance with the axiom already inculcated so often: the more compact the matter that light has obtained, or that which receives and reflects light, the more brilliant it will be.

[Margin: Quare obſcuriores & debiliores Cometæ ſint frequentiores ?] *Why are darker and fainter comets more frequent?*

Very bright and very large comets of this kind, however, occur quite rarely; those of a duller colour occur more frequently. The cause is this: the matter of comets is very rarely condensed so far that such very large and very solid nuclei can be generated, much less that it should compose one single body; for the most part that matter is dissolved before it can reach so great a maturity and solidity.

[Margin: Cur aliusCometarum alio ſit diuturnior ?] *Why is one comet longer-lasting than another?*

3. It is asked why some comets are longer-lasting than others and appear for a longer time, even if you leave aside the heliacal setting of comets. Answer: in our view, those will be longer-lasting which consist of more solid and rather large nuclei and of denser and more tenacious matter, and whose bodies, moreover, possess a very slow motion of congregation and of dissipation; above all those that are reduced to one solid body and display a very slow motion along their trajectory, withdrawing from the Earth only little by little. The remaining comets, by contrast, consist of more diluted matter and of very few and very small corpuscles that never come together into one solid nucleus, and have besides a very swift motion along their trajectory and of segregation. Those, I say, last for a

short span of time and escape the sight of the eyes very quickly, inasmuch as their matter is easily dissolved and dissipated and reflects the light of the Sun only with difficulty, so that they cannot be seen for long.

[Margin: AnCometarum diameter vera diſcedendo à Terrâ perpetuò minuatur ?] *Does the true diameter of comets continually decrease as they withdraw from the Earth?*

4. It is asked whether the true diameter of comets, as they withdraw from the Earth day by day and are carried more and more into the higher aether, also diminishes from day to day, as is indeed noted, accurately and with the naked eye, in their apparent diameter; or whether instead the true diameter remains always similar to itself and the same in every situation, lower as well as higher. We answer that in certain comets the true diameter continually grows, even as they withdraw more and more from the Earth, and very rarely shows its quantity always the same, although to the naked eye the contrary appears. For when comets have already reached a mature age (which happens to most of them in places nearer the Earth) and are gradually removed farther from the Earth, then, I say, the nuclei begin little by little to separate from one another, and the matter to dissolve and become rarefied, and so to be dilated more and more. From this the true diameter, and also the apparent one, is necessarily found always to grow, if anyone examines it with instruments.

[Margin: Quanta Cometæ 1618 vera diameter diverſis diebus extiterit.] *How great the true diameter of the comet of 1618 was on various days.*

This is clearly proved by the comet of the year 1618. The apparent diameter of its whole disc was estimated on December 1 at only 8′; on December 9 it had already reached a magnitude of 10′; on the 17th, 13′; on the 20th, 14′; and on the 24th, 16 minutes. And indeed this is evident not only from the observed apparent diameter but also from the calculation itself. For if, given the observed diameter and the distance for each day, you compute its true diameter, it will become known that this very diameter actually became larger day by day. But to embrace everything briefly, I shall at once append the sum of the calculation, deduced from Cysat's distances on p. 52 for the same comet, and from the apparent diameter observed with the greatest diligence by the author himself: namely, how great the true diameter was on various days, in German miles.

[Margin: Cometæ 1618 apparens & vera diameter in dies crevit.] *The apparent and the true diameter of the comet of 1618 grew day by day.*

Month, day	Distance from the Earth, semidiameters of the Earth	Apparent diameter, minutes	True diameter from the calculation, German miles
December 1	72	8	144
9	96	10	240
17	132	13	430
20	154	14	540

Month, day	Distance from the Earth, semidiameters of the Earth	Apparent diameter, minutes	True diameter from the calculation, German miles
29	252	16	1010

541

From this it is clear, the calculation having been set up correctly in this way, that the diameter of the comet grew continually. Believe me, this comes about from no other cause than that the nuclei were gradually segregated more and more, and the matter was dissipated and extended into a larger disc, as it were.

[Margin: Quando Cometa quotidie lucidior ſit, indicium eſt, nondum ad maturitatem eum pervenisſe.] *When a comet becomes brighter every day, it is a sign that it has not yet reached maturity.*

But if, in some comet withdrawing from the Earth every day, both the true and the apparent diameter should increase and grow at the same time, and it should likewise appear continually brighter, then I consider that we must conclude that the diameter becomes larger and greater not by reason of the dilation and dissipation of the matter or of the bodies, but from the confluence of several opaque bodies, with new matter coming in on top; and that the head of the comet is thus still engaged, as it were, in accretion and augmentation, and has not yet reached maturity.

[Margin: Cometa 1652, quò magis à terrâ elongat[9], eò magis etiam diameter apparens attenuata eſt.] *The comet of 1652: the farther it was removed from the Earth, the more its apparent diameter too was diminished.*

But, you will say, why was something almost different observed in the comet of the year 1652? For although it became higher and darker day by day, its diameter nevertheless decreased continually and notably, both with the help of instruments and tubes and to the unaided eyes; and this seems to conflict entirely with what was said above. For the matter ought to have been dilated and the corpuscles segregated further, since, as we have said, it became ever more diluted and paler.

[Margin: Reverà diameter ejus in dies crevit.] *In reality its diameter grew day by day.*

Certainly this objection, just as it is not a trifling one, so it deserves to be discussed more fully, as one that seems to contribute a great deal to this business of comets. But it must indeed be understood that the diameter does not always really decrease, even if it seems so in appearance; sometimes the contrary happens. This is quite easy to demonstrate by calculation: if the true diameter of the comet of the year 1652 is properly derived for each day from the

541 on the page the table stands at the head of the page in the left part of the measure, with the first eight lines of the following text set beside it on the right. Its heads read *Menſ.Dies.*, *Diſtant. à terrâ Semid.T.*, *Appar. diamet. Minut.* and *Vera diameter ex calculo Mill.germ.*; the month is printed once, in the first row. A rule divides the first three rows from the last two. The last row gives the 29th, where the text on the preceding page gives the 24th for the same 16 minutes.

genuine distances and the apparent diameter, it will become apparent that this is how the matter stands. Since this has already been done above, on p. 337, and also set out in order in a small table, we can dispense with that labour. If, then, you consult that table properly, you will find that for the first four days the comet remained, as it were, in the same state, but that in the days immediately following it grew continually and in a wonderful manner: just as day by day it grew in darkness and faintness, so it grew in size as well.

[Margin: Cometæ quantò obſcuriores ſunt, tantò illorum diameter major eſt.] *The darker comets are, the greater their diameter.*

So it is nonetheless most true that the more comets fall off in brightness, the more their true diameter actually increases, although as to the apparent [diameter] they continually decrease: which was what had to be investigated.

That in some comets, as in the year 1618, the true and the visible diameter were increased together, while in certain others only the true one was, the visible one decreasing, as in the year 1652, comes about from this: in the former the distance from the Earth changed and increased only very little, while on the other hand the motion of the matter and of the bodies of which the cometary head consisted was extremely agitated, and the proportion of the motion of the nuclei was greater than that of the distances, so that the matter and the nuclei could then easily be dissolved and dissipated. In the latter, however, as in ours, it happened that the distances from the Earth made great and remarkable advances every day.

[Margin: Cur in quibusdam Cometis vera & viſa diameter ſimul creſcat ?] *Why do the true and the visible diameter grow together in certain comets?*

Therefore, even if the apparent diameter, owing to the immense elongation it has acquired, should appear smaller day by day, the true diameter must nevertheless really grow. For this reason, in those com- ets in which the distance from the Earth varies only gradually and slowly, as was observed in the comet of the year 1618, the true diameter always grows together with the apparent one. In the rest, however, where the distance from the Earth changes and increases very swiftly, only the true diameter expands and really increases.

And so it is plain to anyone that, on our view, these phenomena can be saved excellently. But how the Peripatetics could do this very thing I scarcely see: namely, that comets, mostly toward their end, must grow in respect of their true diameter. For they hold that comets are gradually consumed by fire, and hence that in their view the bodies of comets continually decrease, right up to their destruction. This runs against clear observations, which plainly prove the contrary: that comets, at almost every time, mostly around their end, increase in respect of the disc, even though they become more and more obscure, and are so thinned out that they seem to be entirely extinguished.

[Margin: Ex ſententiâ Autoris quævis phænomena feliciter explicantur, & demonſtrantur.] *On the Author's view any phenomena whatever are happily explained and demonstrated.*

[Margin: Peripateticis Cometarum diametri perpetuò diminuuntur, contra manifeſtisſimas obſervationes.] *For the Peripatetics the diameters of comets continually diminish, contrary to the most manifest observations.*

But, you will say, what if we hold that comets keep and preserve the same true diameter all the while, until the matter in them is either consumed by internal causes or vanishes altogether? Shall we not be able to save those appearances just as well? Certainly not. So that you may grasp this the better, come now, let us consider our comet of the year 1652 distinctly. For, once this were granted, it would have presented itself to us far otherwise, and indeed much smaller as to its apparent [diameter] (to say nothing of the rest); and, according to the proportion of its distances from the Earth as it held from day to day, the said apparent diameter would have had to decrease quite otherwise than the observations themselves showed it.

For from what precedes you have, I think, understood well how large the apparent diameter was from the observations: namely, on December 20, 30′; on the 26th, 24′; on January 1, 10′; on the 7th, 5′. Suppose these are taken with the corresponding distances, while the true diameter of 825 miles that the comet had on December 20 is kept the same at all times, and suppose that from these data we seek the apparent [diameter] in this way. We shall find, as we were just saying, that it ought to have appeared far more compressed than was in fact found from the observation itself: so that on the 26th it would have been only 17′ 28″, on January 1 only 2′ 2″, on January 7 24″, and on January 10 scarcely 12″. But who does not see how great a difference there now is between this apparent diameter deduced from the calculation and the one we observed with skill!

[Margin: Apparens diameter Cometæ 1652,quá ratione decreverit.] *How the apparent diameter of the comet of 1652 decreased.*

[Margin: Quanta extitisſet diameter apparens,ſi vera ſemper eadem permanſisſet.] *How large the apparent diameter would have been, if the true one had always remained the same.*

But you will understand all this still more clearly from the table set beside this text. In it, for every day of the apparition, we have computed both the comet's corresponding distance from the Earth and the observed apparent diameter, and also the apparent diameter derived from calculation, keeping, as we indicated, always the same true diameter, namely 825 miles.

Year 1652, days	Distance of the comet from the Earth (semidiameters of the Earth)	Apparent diameter observed	Apparent diameter from calculation, always keeping the same true diameter

542

You see, then, my Reader, that on these suppositions the apparent diameter would have varied by many minutes, so that, with the comet's true size always taken as the same, the apparent [diameter] would have been reduced to very few seconds within the space of only a few days; whereas it is established from observation that at that same time it was still of many minutes. It follows, therefore, that if things stood so, the comet would have withdrawn itself from our sight much sooner. For when the comet, with its apparent diameter still 4′ or 5′, scarcely met the eyes even of those endowed beyond others with an exceptional keenness of sight, what, I ask, would have happened if it had had only 10″ or 20″ in diameter? Would it not already have vanished entirely on December 30? Indeed, if you weigh the matter rightly and bring it to calculation, you will readily admit that it could scarcely have been seen on the 29th: for at that time it was already so thinned that it was only 6′, as we have found from the preceding table. Yet nothing is truer than that the comet was seen for a long time indeed, by almost everyone. What of the fact that [it

[542] on the page this table stands at the left of the measure, with the last 24 lines of the text set in a narrow measure to its right; it has no caption. The Latin heads are "Anno 1652 Dies"; "Diſtant. Cometæ à Terrâ S. T."; "Diam. appar. obſervata."; "Diam.appar. ex calc. ſerv. ſemper eâdem diamet. verâ." Columns 3 and 4 each print the minutes and the seconds as two figures under the sub-heads given in the second row, with no rule between them. Column 1 prints the day of the month only; the days run from December 20, 1652, and "An.53." (the year 1653) is set before January 1. A rule crosses the table after every third row.

was seen] still on January 7 and 8? Therefore this comet in no way kept the same true size of its disc throughout. Nor do I think that any others ever either appeared or can appear (if, that is, they recede continually more and more from the Earth, become more obscure and paler, and tend toward their destruction) that can always keep their true diameter equal to itself.

[Margin: Si diſcus in dies decreviſſet multo citiùs diſparere viſus fuiſſet Cometa anni 1652.] *If the disc had decreased from day to day, the comet of the year 1652 would have seemed to disappear much sooner.*

[Margin: Nec Cometa 1652 nec unquam alios apparuiſſe eandem continuò diametrum veram ab initio ad finem conſervantes.] *Neither the comet of 1652 nor any others ever appeared keeping the same true diameter continuously from beginning to end.*

So much less, then, did this same comet decrease in respect of its disc and its true diameter (and I would have the same said of almost all the others too). For if the disc had really been diminished from day to day, it would have vanished much sooner still, so much so that it would barely, if at all, have appeared for 5 or 6 days, as the calculation plainly shows and as everyone will find from the table set beside this.

In this table the apparent diameter has been computed for several days, given, that is, the corresponding distance and the true diameter, decreasing daily by 100 miles. From these data, however, the apparent [diameter] came out far smaller than it really was by observation. For already on December 25 it would have been seen no larger than 8′ and no brighter than it actually was on January 2; on December 26 the comet's diameter would have been reduced to 4′, the size at which it still appeared to us on January 10; and on the 27th it would have been so thinned that it could in no way have been perceived by the eyes, since it would have had only 1′ 30″ in diameter. And so within the space of 24 hours it would have become entirely imperceptible.

[Margin: Si diameter Cometæ 1652 ſingulis diebus 100 mill. decreviſſet, die Decemb. jam evanuiſſet.] *If the diameter of the comet of 1652 had decreased by 100 miles each day, it would already have vanished on December*[543].

Year 1652, December	Distance of the comet from the Earth (semidiameters of the Earth)	True diameter in German miles	Hence the apparent diameter
			Min. Sec.

27	265	100	1′ 30″

[543]the side-note prints no day of the month here

544

But the matter will become clearer still if we suppose that the comet decreased, as to its true diameter, in exactly the same ratio in which it in fact grew. Then it would certainly have seemed to us to perish far sooner.

Year 1652, month, day	Distance of the comet from the Earth (semidiameters of the Earth)	True diameter of the comet in miles	Apparent diameter of the comet
			Min. Sec.
Dec. 21	110	825	30′ 0″
22	111	804	28′ 50″
23	114	800	24′ 4″
24	124	794	21′ 44″
25	146	686	14′ 30″
26	189	466	7′ 0″
27	265	48	0′ 30″

545

Suppose, as we said, that the comet really decreased in the proportion that the table set beside this reports, so that on the 27th its diameter would have been only 48 miles; then the apparent diameter, the calculation having been duly carried out, on the 26th of Decem- ber would have been 7′, and on the 27th only 30″. Hence on the 26th the comet would indeed have met the eyes clearly, but on the 27th it would have been entirely extinguished in a moment, as it were, like a flash of lightning. From this it is at the same time easy to show how suddenly and unexpectedly comets can sometimes be born and pass away, if they grow or decrease in such a manner, as will be said more fully in the following Book, on the generation and corruption of comets.

[Margin: Poſſunt nonnunquam ſubitò Cometæ in conſpectum prodire, ac iterum viſui ſe ſe ſubducere.] *Comets can sometimes come suddenly into view and withdraw themselves from sight again.*

5. Further, granted this hypothesis of ours, we also readily perceive how the origin and destruction of comets come about, and how they acquire a perfect consistency. For when a certain rarer matter, and other, denser corpuscles, are gathered together and condensed, and form as it were

544 on the page this table stands at the right of the measure, beside the eight short lines of text that begin "In this table"; it has no caption. The Latin heads are "An.1652 Decemb."; "Diſtantia Com.àterrâ. S. T."; "Diam. vera inMill. German."; "Diam. ergo Apparens Min. Sec.". Column 4 prints the minutes and the seconds as two figures, with no rule between them. A rule crosses the table after the fourth row. In column 2 the distances for the 20th, 21st and 22nd are printed 100, 100¾ and 111¼, where the table on the preceding page and the table below give 110, 110 and 111.

545 on the page this table stands at the left of the measure, beside the six short lines of text that begin "Suppose, as we said"; it has no caption. The Latin heads are "An. 1652 Menſ. D."; "Diſt.Com. à ter.S.T."; "Diamet. vera Com. in mill."; "Diam.app.Com. Min. Sec.". Column 4 prints the minutes and the seconds as two figures, with no rule between them. A rule crosses the table after the fourth row.

a heap of nuclei, then the comet is, so to speak, first born, and offers itself to be seen by us, unless too great a distance from the Earth prevents it. But when that matter in turn — partly the transparent cometary [matter], partly the nuclei, as the denser parts — is separated, dissolved and thinned out, then the comet vanishes. To put it more briefly still: a comet arises from the condensation and accretion of a certain matter, and also from the gathering and packing together of corpuscles; conversely, it is extinguished by the dispersal, dissolution and thinning of the matters and of the nuclei.

[Margin: Quâ ratione Cometæ oriantur ac occidant.] *In what manner comets arise and perish.*

In the same way the sunspots too take their increase and decrease in the atmosphere of the Sun, and by them this business of comets is elucidated best of all. For they likewise are generated solely from the flowing together or flowing apart of a certain denser matter, and from the concurrence, coagulation and condensation of several opaque bodies; and in turn they perish by thinning, dispersal and disjunction. For when some spot is to arise physically, first a matter is seen in that same place like a very faint shadow, but sometimes very large, and spread and diffused very widely. Afterwards it gradually gathers and coalesces and is pressed more tightly together, until from that same packed matter very diverse nuclei, not rarely, are generated, gradually growing in bulk; and from their flowing together and concurrence, with other new matter also coming on top, spots that are huge and of astonishing size take their origin. But if the said nuclei and those minute corpuscles, together with the thinner matter adhering to them, are suddenly separated again and dissolved, the spot of the Sun readily perishes without warning, and no notable one is produced. It has also mostly been noticed that, when the larger spots tend toward their physical destruction, their larger nuclei are resolved and dispersed into several very small ones, which afterwards gradually separate and move away from one another, until the matter itself is reduced, as it were, to nothing by thinning. But we shall treat of these more fully later, in their proper place. For these sunspots can certainly be of no small use in thoroughly examining the matter of comets.

[Margin: Cometæ cum maculis Solaribus optimè conveniunt.] *Comets agree very well with the sunspots.*

[Margin: Quomodo Maculæ Solares generentur, ac disſolvantur.] *How sunspots are generated and dissolved.*

6. It is asked whether the disc of all comets is at all times perfectly round. The answer is no. For since comets, on our view, consist of many very diverse, indeed sometimes innumerable, corpuscles and nuclei, it can by no means happen that the joining and gathering of the bodies, and likewise their accretion, which comes about in such diverse ways and at diverse times, should be so regular that, entirely to the absolute figure of a circle, with always the same propor-

[Margin: An Cometarum diſcus ſemper ſit rotundus ?] *Whether the disc of comets is always round.*

tion kept, it could approach. Rather, what then mostly happens is that more matter accrues here and there, and from this various prominences, protuberances, concavities and very irregular windings come to exist in that cometary body. Such [features] without any doubt really existed in these two comets of the years 1618 and 1652 as well, so that for this reason they were by no means perfectly round. That they nevertheless appeared almost round came about from their immense distance from the Earth: in such a position even entirely irregular bodies present an absolute roundness, as optics demonstrates.

7. It is asked further whether those nuclei, or corpuscles, or those little stars, of which the cometary body is composed, are of perfect roundness. Again the answer is no. For in my opinion at least, none at all of the planets, which draw their light from the Sun, is or can be of an absolutely round body, but [each is] of a rough and uneven one: otherwise it would by no means reflect a universal light to us, as has been clearly demonstrated in optics and in our *Selenographia*, Chap. VI. Just so, those nuclei too, which make up the head of the comet, are irregular bodies having their own roughnesses, concavities and protuberances; and if they lacked these, no universal reflected light of the Sun would be noticed from them either.

[Margin: Nec nuclei, ex quibus caput Cometicum conſtat perfectæ ſunt rotunditatis.] *Nor are the nuclei of which the cometary head consists of perfect roundness.*

Although I readily grant that this very thing cannot so easily be demonstrated by us in the comet of the year 1652, because those nuclei were so slender that they almost eluded sight, it is nevertheless to be plainly established from Cysat's comet, which shone in the year 1618, that it had nuclei of irregular figure: for on December 8 he accurately found it [to consist] of three irregular nuclei cohering with one another. Yet I do not altogether deny that there can sometimes also be corpuscles that are round to some extent, indeed some rounder than others, but not all: as usually happens in the sunspots, in which the nuclei are mostly irregular, though some surpass others in roundness, and some come closer than others to a more absolute roundness — never, however, or only very rarely, to an entirely perfect spherical [roundness], but only to such as pepper and corpuscles of this kind display. Although these have very many concavities and little cavities, yet, seen from a distance, they can in no way be distinguished; rather, you would judge them to be perfectly round bodies.

[Margin: Cometa anni 1618 nucleos habuit irregulares.] *The comet of the year 1618 had irregular nuclei.*

We have therefore shown abundantly, kind Reader, how matters stood altogether with the heads of the comets of the year 1618 as well as of the year 1652; and that we are entirely of the opinion that the same happens with all other genuine comets too (excepting apparitions and meteors of the air, which are sometimes taken for comets, but wrongly): namely, that they are composed of

very diverse irregular corpuscles, which in their time are gathered together and condensed, and in turn are separated, dissolved and dispersed, as we discussed more broadly above. This can indeed be demonstrated in certain other comets as well. For we learn from the history of comets that several of the same kind have existed whose heads were formed not from one body but from several, and which likewise afterwards went off into different parts, and those parts were gathered together again. Among their number is rightly counted the comet that Nicephorus mentions in Book 12, Chap. 37 of the *Hist. Eccles.*, which shone a little before the strangling of Valentinian, in the year of Christ 392:

[Margin: De Cometâ Nieephori.] [recte: Nicephori] *On the comet of Nicephorus.*

"Then indeed," he says, "unusual portents were also seen, etc. For first an unexpected and unaccustomed star appeared in the sky at midnight, shining near the Morning Star [Luciferum], around that very circle which is called the zodiac. Because it was huge and bright with its flashing rays, it did not yield much to the Morning Star. Little by little, moreover, a huge mass of other stars also gathered to it. Had you seen that spectacle, you would have compared it to a swarm of bees flying in a circle round their leader. And the light that flashed out from all of them, as if from a mutual and violent collision, mingled into one single flame and presented the appearance of a great and dreadful two-edged sword, shining with a certain terror. For it was seen that the remaining stars fell back into the same [place], and that one star, and it alone, the one that had first been seen, appeared in its whole bearing like a root or a kind of hilt, and in some manner gave forth the brightness of that star that had been displayed; and just as a burning wick from a lamp, so the flame was raised on high."

Aristotle reports almost the same in Chap. VI of the book of the *Meteorology*: namely that Democritus held that comets are sometimes resolved into stars: "Democritus contended for his opinion, for he says that when comets were dissolved, certain stars appeared."

[Margin: Quâ facie Cometa an. 1652 in Americâ apparuerit ?] *In what appearance did the comet of the year 1652 appear in America?*

An almost similar example was observed in the case of the comet of the year 1652 in America, in a certain Parensian [Parenſi] city, commonly called Chuquiabo. Father Joh. de Königk of the Society of Jesus wrote of it to the celebrated Kircherus [Athanasius Kircher], and he in turn wrote to me on 1655 January 30: namely that in 1652, on December 15, new style, a twin comet appeared, with crossed tails, and with a third, very small one darting out from one of them. From this it is conjectured — provided, that is, that they did not stand far apart from one another (about which, however, the author reports nothing certain) — that they afterwards grew together into one body. For here in Europe only a single comet was seen a little later, namely on December 18 and 20; and in that form Father Königk himself also observed the comet at Cusco, and others too at Lima, Chuquisaca, Potosí and Oruto. So it is clear

from this that around its first rising there were two or three comets, but shortly afterwards only one appeared.

[Margin: Quinam ex veteribus, ſtatuerint Cometas ex diverſis conſtare corpuſculis.] *Which of the ancients held that comets consist of various corpuscles.*

Since, therefore, it has been handed down to memory that various examples of this kind have occurred, many of the older as well as of the more recent [writers] have for this reason embraced the opinion that the bodies of comets consist of various corpuscles and nuclei: for instance Anaxagoras, Democritus, Apollonius Myndius, Seneca, Zenon, Cardano, Cornelius Gemma, Jordanus Bruno [Giordano Bruno], Tannerus, Tycho, Mästlin, Helisæus Roslinus [Helisaeus Röslin], Tadeáš Hájek, Marcellus Squarcialupus, Ambrosius Rhodius, Thomas Fienus, D. Habrecht, Kepler, Snel, Erycus Puteanus, Liceti, Fromondus, Franciscus de Resta, Cysat, Libavius, Cabæus, Longomontanus, Eichstadius and very many others. And yet almost all of them, one and all, disagree greatly among themselves, and nearly every one of them holds his own particular opinion on the generation and corruption of these bodies.

[Margin: Variæ Veterum Opiniones de Cometis.] *Various opinions of the ancients on comets.*

For some think that the bodies of comets consist of old fixed stars, known long since, gathered together into one heap; others, of new stars created by God in the beginning; others, that they are a particle of the Milky Way; others, [that they are] consolidated aether; others again, that they draw their origin from the spots and faculae of the Sun — to pass over the remaining opinions, about which it is not to the point to say more here. For we have resolved, God willing, to record and examine these matters more clearly elsewhere. But what we ourselves think about these corpuscles and about the matter of comets — namely, from where it comes forth and takes its origin, and how comets really are born and perish — we shall set out at greater length in the next Book, where their origin and passing away will be treated expressly. To that Book are reserved many most useful and very difficult questions which could not yet be untangled in this Book.

End of Book VI [FINIS LIBRI VI.]

Johannes Hevelius, Cometography, Book Seven [JOHANNIS HEVELII COMETOGRAPHIÆ LIBER SEPTIMUS.]

On the Origin, Genuine Matter, Form, Properties and Passing Away of the Comet of the Year 1652 as well as of All Others [De Cometæ,tam anni 1652,quàm aliorum omnium ortu, genuinâ materiâ, formâ, proprietatibus, & interitu.]

[Margin: Autor ſtatuit Cometas univerſos verſari in æthere.] *The author holds that all comets move in the aether.*

Since, therefore, the order of the work now seems to require that we treat of generation and corruption not only of our own [comet] in particular but of

all comets in general, it will not be out of place to point out at the beginning what we have already impressed many times in this work of ours, almost to the point of satiety, and have abundantly demonstrated: namely, that comets are placed not in our sublunary air but far above the Moon, in the highest aether, just like all the wandering celestial bodies; and that in it, like birds in the air and fish in the water, they have performed their motions most freely, without any resistance — in that most liquid and limpid ethereal matter, that is, which differs from our air only in purity. In it no solid and real orbs at all are found, as has indeed been loudly proclaimed both in the old age and by not a few of the more recent [writers] even now. But about this we shall speak at length in its proper place.

[Margin: In Cœlo nulli orbes reales dantur.] *There are no real orbs in the heavens.*

[Margin: Quid ſint Cometæ,ex mente Peripateticorum & Ariſtotelis.] *What comets are, in the view of the Peripatetics and of Aristotle.*

Since this is really so — namely, that all the ethereal matter poured round the celestial bodies is not in the least solid but supremely liquid, and that comets have moved in that same ethereal region far above the Moon — we shall therefore labour in vain if, with the whole troop of the Peripatetics, we go seeking the genuine matter of comets in these sublunary [regions], let alone in the very bowels of the Earth. The Peripatetics are thoroughly convinced that the matter of comets is a hot and dry evaporation, drawn up from the arid and dry earth into the highest region of the air; or rather, following their supreme leader Aristotle, that it is a hot and dry exhalation, smoky and somewhat fatty, fit to catch fire.

[Margin: Cometarum materia, circa corpora ætherea quærenda eſt.] *The matter of comets must be sought among the ethereal bodies.*

But in truth we must aim our thoughts much higher, and seek the origin of comets, and their matter and birth, nowhere but in the starry heaven, among those ethereal bodies. For their bodies certainly consist not of nothing at all but of some definite matter, since nature produces nothing without matter. But to imagine a body without matter is the mark of no philosopher, but of the most foolish of men: unless you would rather count the substance of comets, their origin and passing away, and all their attributes among the secrets of nature and the occult qualities; or [unless] we choose to ascribe them either to God, the Founder and Ruler of all things, or to certain Intelligences.

[Margin: Res naturales adDivinam referre omnipotentiam dedecet prorsùs Philoſophum.] *To refer natural things to divine omnipotence is wholly unbecoming to a philosopher.*

That, however, is wholly unbecoming to a natural philosopher: namely, to refer natural things straight away to divine omnipotence, or to take refuge at once in the asylum of the Intelligences — or, more truly, of ignorance — above all if other physical reasons perhaps still remain, by whose help their phenomena can be saved quite successfully. It will therefore be wiser for us to

stay a little while within the bounds of nature, leaving no stone unturned, so that we may see how far it is granted to reach in this matter. For the way of taking refuge in that sacred anchor, when no further remedy is left, will never be closed to us.

[Margin: Phyſicas reddere cauſas in Cometarum negotio res profectò ardua eſt.] *To give physical causes in the matter of comets is truly a hard task.*

It would indeed be a very easy matter if we were to lay down that comets are newly created by God through divine power, and began straight away from their creation: these lengthy disputes, believe me, would soon be brought to an end without much trouble. On the other hand, it must truly be admitted frankly, with many most distinguished men, that if we do otherwise and search out physical causes in this matter of comets, the task is very hard and wonderfully intricate. Accordingly both the greatest philosophers and mathematicians have, from the beginning until now, struck hard against this rock. And however much they have toiled over these matters, even to the utmost, and in devising almost innumerable opinions have left almost nothing untried, nevertheless scarcely any opinion remains in which nothing whatever is lacking, not to say one that deserves everyone's applause.

[Margin: Vtut vix omnibus hâc in parte à quopiam ſatisfieri poſſit, nihilominus tamen ſtrenuè deſudandum eſt, quò negotium iſtud magis magisq́; penetretur,clariusq́; reddatur.] *Although hardly anyone can satisfy everyone on this point, one must nevertheless toil vigorously, so that this matter may be penetrated more and more and made clearer.*

Therefore, well-disposed reader, I by no means persuade myself, nor would I have you persuade yourself — since I am not in the least to be compared with those great and most perspicacious men who have already toiled through this labour with so great an effort, and I am very well aware how meagre my stock of learning is — that I have firmly resolved to bring forward in this matter something most perfect in every respect and in every way most certain. Far from it, far from it indeed! Yet one should not lose heart altogether on that account; rather, we hold that we must strive with all our strength so that at least such things are brought forward as are not wholly absurd and [do not] seem utterly contrary to reason. I rely on the most certain hope that, with divine grace breathing upon [me], I shall make this matter somewhat clearer, at least in some respects if not in all; and that I shall treat the whole business — with both our own comet and certain others holding the torch before us — in such a way that our opinion may not seem to be the most absurd of all, much less to beget spurious and false consequences, but much rather to rest firmly on observations and phenomena. If we achieve that in these most difficult and highest matters, so far removed from our senses and imperceptible to them, we consider that we have fully done our duty, according to our small measure. But if you, kind reader, or anyone else, should be able to set before the world a truer opinion, by which the phenomena can be explained and untangled more correctly and more easily, not only will you be entirely free to do so, but I

myself, believe me, will embrace it with both hands in its time. For though Plato is a friend, and Aristotle a friend, yet Truth is a greater friend.

[Margin: Vt metcora in aëre, ſic nova aſtra & Cometæ in æthere procreantur.] [recte: meteora] *As meteors are produced in the air, so new stars and comets are produced in the aether.*

Since, therefore, the matter and birth of comets must now be sought by us in the highest aether, you can certainly conjecture easily, even if you view the matter only through a lattice, that we cannot declare otherwise than that both comets and new stars are generated, grow, decrease and are corrupted there — just as the new stars remain motionless in it, while the comets perform their motion in the same place — and that these adventitious bodies of the heavens are produced in the aether, among those eternal celestial bodies, in almost the same way as all meteors are produced around the Earth, namely in our sublunary air.

[Margin: In Cœlo dari generationem & corruptionem.] *There is generation and corruption in the heavens.*

From this it follows that the heavens are alterable, and that there is generation and corruption in them, increase and diminution, and alteration. Just as this doctrine is most strongly opposed to Aristotle's teaching on the heavens, so, believe me, it will not please the followers of that philosophy in the least. Nor, indeed, is that surprising, since it seems to destroy his whole philosophy and to overturn its foundations completely.

[Margin: Prægnantibus rationibus & indubitatis obſervationibus auctor adductus eſt, ad hanc ſententiam fovendam.] *The author was led by compelling reasons and indubitable observations to hold this opinion.*

But whatever the case, I cannot give up what I have begun, since I have been persuaded by compelling reasons and by the judgement of the senses, and led to this view: namely, that just as comets move in the heavens, so they also arise there and take their origin there. To this was added the fact that I have been convinced by indubitable observations, my own as much as those of many others, and have learned, that still more generations and corruptions of this kind are detected in the heavens besides. Not only are there stars newly born in the aether itself — some of them seen in their time growing and decreasing, which have long since perished, others still remaining motionless even now among the fixed stars themselves; among these one especially remarkable star occurs, which has now appeared in the Neck of Cetus for some years up to this very day, growing and decreasing (we have dealt with it expressly in a separate booklet) — but almost innumerable solar spots and faculae are also generated and corrupted near the Sun itself.

[Margin: Senſuum judicio ſtãdum eſt, ubi de re ſenſibili philoſophandum eſt.] *One must stand by the judgement of the senses when philosophizing about a sensible thing.*

Since, then, this way of philosophizing does not displease even Aristotle himself — for he bids us stand by the judgement of the senses where a sensible

thing is under discussion, and moreover wants the demonstration of a doubtful matter to rest on principles known through themselves and manifest to the senses — his disciples should not hold it against us if we enter on their master's path in philosophizing and arguing, laying down only what the observations themselves confirm and what experience and the senses clearly teach us: "from which, on pain of weakness of intellect, it is not permitted in the Peripatos to appeal," as Fortunio Liceti, that far from ordinary philosopher, rightly and aptly says in Book V, Chap. 68, p. 312 of *On New Stars and Comets*.

[Margin: Senſus principium eſt omnium noſtrarum cognitionum.] *Sense is the principle of all our cognitions.*

Likewise on p. 306 of the same book, Chap. LX: "Aristotle does not appeal from the senses." "For sense," as the same author advises in Book I, Chap. 2, p. 3, "just as it is the principle of all our cognitions, so it supplies us with true and solid foundations for acquiring knowledge of the most hidden things." Indeed, whatever escapes the senses is not known by the intellect either. If, then, we tread in these footsteps and follow this thread of Ariadne, we are admitted into the hidden inner sanctuaries without straying and without danger.

[Margin: Quid ſit Cœlum eſſe corruptibile & alterabile?] *What does it mean that the heavens are corruptible and alterable?*

But before we go on with our undertaking, it will be worth the effort first to explain our meaning correctly: how those statements are to be understood, when we have said that the heavens are corruptible and alterable, and that there are generations and corruptions in them. But there is no reason for you to persuade yourself that by this form of speech I maintain that the heavens are subject to generation and corruption as a whole; rather, [I] firmly maintain that this can happen only with respect to certain parts.

[Margin: Cœlum non ſecundùm totum ſedquasdam ſolummodò partes generationi & corruptioni obnoxium eſt.] *The heavens are subject to generation and corruption not as a whole, but only in certain parts.*

Indeed, just as this earth of ours and all sublunary things are generable and corruptible — not, to be sure, in respect of the whole, but only in respect of certain of their parts — so too is it with all the celestial bodies and with the whole heaven. For sublunary things can be compared with ethereal ones best of all, because, if we weigh the matter properly, they have a great kinship and a good many common inclinations and affections [paſſiones]; indeed, in very many respects they differ from one another very little, except in purity and tenuity and things like these.

[Margin: Vt Terra,ſic & Cœlum ex uno eodemq́; principio,ex iisdemq́; conſtat elementis.] *Like the Earth, so the heavens too consist of one and the same principle and of the same elements.*

For, first, the whole machine of the world — both the terrestrial globe and the heavens themselves, the former with all things whether animate or vegetable, the latter with each of the ethereal bodies, whatever are contained in this body of the world — was made and created by God, Best and Greatest [D E O O.

M.], out of that chaos created in the beginning. Just so, they also consist of one and the same principle and of the same elements. For I am entirely of the opinion that all the elements, such as fire, air, water and earth (if there are that many), as the principles of all things, or the prime matter, already lay hidden in that chaos, and that only afterwards were they separated, and transferred and distributed by the Creator himself into the bodies of the world, according to the condition and quality of each thing.

[Margin: Omnia Mundana corpora ad eandẽ divinæ artis amuſim eodem modocondita ſunt.] *All the bodies of the world were founded in the same way, to the same rule of divine art.*

From this we conclude, not wrongly: just as the whole of nature consists of one and the same principle, so too all the bodies of the world (as Kircher rightly and excellently says in the *Itinerarium Extaticum*, p. 24, in the Hortatory Prelude [Præluſione Paræneticâ]) were founded in the same way, to the same rule [amuſim] of divine art. They do not differ from one another in any respect as regards elemental matter, but are at variance with one another only through the diversity of their forms and properties. It is no different on the terrestrial globe: although innumerable species of things are found there to differ in forms and properties, all of them are nevertheless found to be the same as regards elemental matter.

[Margin: Materia illa, quæ Mundana corpora univerſa ambit,liquida, ejusdemq́; rationis & naturæ eſt, niſi quod puritate & tenuitate differat.] *The matter that surrounds all the bodies of the world is fluid and of the same character and nature, except that it differs in purity and tenuity.*

Second: it has been clearly established by reason and experience, by almost innumerable astronomers as well as philosophers — namely by the Venerable Bede, Verulam, Tycho, Clavius, Snel, Kepler, Ludovicus Molina, Scheiner, Borrus and Cabæus, to say nothing of almost innumerable others — that this matter, which surrounds all the bodies of the world, the Earth as well as the stars, and fills the whole space between the lower and the upper waters, as we have already said many times, is supremely fluid, and is one and entirely the same, that is, of the same character and nature; except that it is distinguished to some extent by purity and tenuity, so that the sublunary air surrounding the Earth is a little more dreggy [fæculentior] than the aether surrounding the celestial bodies.

[Margin: Æther non niſi puriſſimus eſt aër.] *The aether is nothing but the purest air.*

And, to take in everything in a word: there is one and the same medium from our Earth up to the outermost fixed stars; the aether, or ethereal air [auram æthream], is nothing but the purest and thinnest air, and conversely air is nothing but somewhat thicker aether.

[Margin: Vbi eadem materia, ibidem etiam eadem eſt eſſentia.] *Where there is the same matter, there too is the same essence.*

From this it is rightly inferred again and again that where there is the same matter, subtlety and transparency [diaphania], there too is the same essence. But there are generations and corruptions in the sublunary air; therefore there certainly are in the aether too, which, as we have impressed on you many times already, is nothing but the purest and thinnest air. The sum of it comes to this: since no material, and formal, difference between air and aether intervenes, and nature itself also recognizes no difference at all here, generations and corruptions occur alike in the air and alike in the aether, as in a similar medium of the world — and consequently both around the Earth and around all the celestial bodies — according to the condition and property implanted in those bodies by nature: not, to be sure, as a whole, but only with respect to certain parts, as will become more properly evident from what follows.

[Margin: Tellus noſtra innumeris penè generationibus & alterationib[9] eſt obnoxia.] *Our earth is subject to almost innumerable generations and alterations.*

Moreover, daily experience teaches us that both the earth itself, as regards certain parts, and its atmosphere are, by a certain natural necessity, subject to many most diverse and almost immeasurable generations, alterations and corruptions, without which, certainly, it could not otherwise subsist.

[Margin: Varii generis Meteora obſervantur.] *Meteors of various kinds are observed.*

[Margin: Meteora alia ſunt terrea, aquea, aërea, & ignea.] *Some meteors are earthy, [others] watery, airy, and fiery.*

For — to touch here only on those things, and to call them back to mind, that happen around the Earth, in its atmosphere and the sublunary air, by reason of exhalations and vapours (leaving out all those that occur both on the surface and in the bowels of the earth, around trees, plants, animals, buildings, metals, etc.) — we observe that many meteors of various kinds, earthy, watery and airy as well as fiery, are generated in those various regions. To say nothing at all for now of the earthy and airy ones, among which the wind and the threads of the Blessed Virgin [fila D. Virginis] are elsewhere counted, and to note only some of the watery ones, namely the principal ones: there are found mist, hoarfrost, clouds, snow, rain, hail, dew, etc. Of the fiery ones, however, far more occur, above all if it were necessary to mention each and every one here.

[Margin: Meteora ignita quædam in inferiore aëris regione, quædam in ſuperiori generantur.] *Some fiery meteors are generated in the lower region of the air, some in the upper.*

Among others, namely: in the lower region of the air, the flying dragon, the ignis fatuus, the licking fire [ignis lambens], the star Helena, Castor and Pollux, etc.; in the middle region of the air, the falling star, the burning lance, the thunderbolt, etc.; and in the highest region of the air, the torch, the perpendicular fire, the bolis, the leaping goat [capra ſaltans], flying sparks, the beam, etc. These meteors, I say — together with all the rest, which are deliberately passed over to save paper — arise only from the vapours and exhalations of the terrestrial globe. That is, the earth continually breathes them out in every

direction, all round, into its atmosphere and perpetually emits them; and it draws them back again, or they are pressed down to the earth by the force of the Sun's rays — more copiously and strongly, however, at one time than at another, according to the constitution both of its own body and of the Sun and the stars, which now greatly promote these exhalations and effluvia, now hold them back.

[Margin: Terra quo fine exhalationes in atmoſphæram continuò exſpiret.] *For what purpose the earth continually breathes out exhalations into the atmosphere.*

[It does so] to this end: partly that the air, which is supremely wholesome to plants and to all animals and most necessary to common life, may be purged, stirred up and sharpened; partly that the generations of sublunary things may be assisted universally.

[Margin: Circa corpora ætherea ſimiles, pro cujusvis corporis ratione, generationes & corruptiones accidunt.] *Around the ethereal bodies similar generations and corruptions occur, according to the nature of each body.*

It is almost the same with the other bodies of the world and the ethereal bodies: in them and around them, no less than on the Earth and in the atmosphere surrounding it, manifold generations, alterations and corruptions occur, according to the nature of each body. And yet it must not be denied that changes similar to our earthly ones cannot be detected in the celestial globes themselves, or on their surface, either with the naked eye or with the armed eye; indeed, although some may perhaps be present there, they nevertheless elude all keenness of sight. The chief reason is this: that because of their immense distance from us, this can by no means happen. Since no telescope at all has yet been invented, or is ever to be hoped for from human industry (in my judgement at least), by means of which reaching that far would be possible, so that all those things, each and every one of them however small, that exist on any body of the stars might be distinctly perceived.

[Margin: Vix Telèſcopium ullâ ratione expolietur unquam, quo quævis minima in globis cœleſtibus extantia deprehendi poſſint.] *Hardly will a telescope ever be perfected, by any means, through which even the smallest things standing out on the celestial globes could be detected.*

For this reason I hold it plainly wrong to settle anything certain about these things: even if reason does not altogether forbid it, it nevertheless by no means comes within the reach of the senses. But with regard to those generations and corruptions that occur around the ethereal bodies, in their individual atmospheres, the matter is far plainer, and for us entirely certain, because observations and the senses teach and demonstrate that these things are plainly so, as will soon become evident from everything that is to be said below.

[Margin: Vniverſa corpora cœleſtia ſuas habent atmoſphæras, in quibus ſuo modo generationes & alterationes accidunt.] *All the celestial bodies have their own atmospheres, in which generations and alterations occur in their own way.*

These generations and corruptions of which we are now speaking take their origin in almost the same way as those around the earth: namely from the effluvia of vapours and exhalations, which those ethereal bodies — being, like the earth, solid and opaque, and consisting of heterogeneous parts — likewise perpetually emit into their adjacent atmospheres [athmoſphæras] and breathe out all around.

[Margin: De exhalationibus & effluviis æthereis, quâ ratione ex corporibus effluant.] *On ethereal exhalations and effluvia: in what way they flow out from the bodies.*

These effluvia, however, are not altogether of the same kind. Rather, each body, according to its own condition and constitution, throws out various ones, as our earth does: now vaporous expirations [exſpirationes], now hot and dry ones (so to speak), now others of a different kind, according as [the bodies] differ from one another by the diversity of their forms and properties. Next, they also differ in this: that some breaths and outflows are now subtler and thinner than others, now denser and thicker. In accordance with this diversity, therefore, and with the differing nature implanted in them which those expirations possess, the lighter or the heavier they are (if I may be allowed to speak thus in our usual manner), the more or the less they move away from the body from which they issue, and are carried higher into the atmosphere and rise.

[Margin: Quinam Autores à partibus ſtent Autoris.] *Which authors stand on the author's side.*

In this, indeed, not a few of the learned agree with us: namely Plutarch, in the little book on the face of the Moon; Cornelius Gemma, on the portentous appearance of the comet of the year 1577; Kepler in the *Optical Part of Astronomy*, and also in the description of the new star in Serpentarius; Scheiner in the *Rosa Ursina*; Simon Marius in the *Mundus Jovialis*; Cabæus in the Commentary on Aristotle's books of *Meteorolog.*; Soares in the *Cursus Philosophicus*; Gassendi in the *Philosophia Epicuraea*; Kircher in the *Itinerarium Exstaticum*; and many others. Among their number — to say nothing of Pythagoras, Heraclitus, Thales, Plato and Proclus — a great many Fathers of the early age are also rightly counted, who asserted that the heavens do indeed consist of elements: namely Tertullian [Tertulianus], Basil, Ambrose, Jerome, Augustine, Theodoret and Cyril, a long catalogue of whom Martinengus gives in the great Gloss, vol. 1 [Tom. I.]; but to list them all here would take too long.

[Margin: Quâ ratione corpora ætherea juxta autorem evaporationes exſpirent.] *In what way, according to the author, the ethereal bodies breathe out evaporations.*

But so that you may grasp our meaning still more clearly: I hold firmly in my own mind that every ethereal body continually casts out and throws off exhalations and evaporations, or effluvia, from every part of its body — the thicker exhalations only into its adjacent atmosphere, but the thinner and purer

ones sometimes even beyond that atmosphere, into that most spacious ethereal field; though at some times in greater abundance and quantity than at others.

[Margin: Exſpirationes æthereæ diverſi ſunt generis, & qualitatis.] *Ethereal expirations are of different kinds and quality.*

These expirations and evaporations, likewise, are also of different kinds according to their inborn nature, and perhaps also of different quality: now dri- er [ones], which coalesce with difficulty; now moister and fattier [ones], which readily come together and condense. And, according to the condition of the matter, they form now subtler corpuscles, such as clouds and little clouds, now denser bodies, some of which are more durable and more tenacious than others.

[Margin: Ex tenuiſſimis corporum Cœleſtium effluviis Cometæ procreantur.] *Comets are produced from the very thin effluvia of the celestial bodies.*

From these effluvia and exhalations of the celestial bodies, I say — which at first are indeed extremely thin, indeed much thinner than our vaporous air, so that before they are condensed and consolidated they can in no way be perceived by the eyes — comets and new stars are also sometimes produced, now smaller, now larger in body and bulk, according as that matter is more plentiful in that part of the heaven, coagulates more readily, thickens and flows together copiously, and as the corpuscles and nuclei newly generated from it are gathered abundantly into one heap and are packed and consolidated more tightly.

[Margin: Exhalationes illæ Cœleſtes naturalem habent facultatem generationis, & corruptionis.] *Those celestial exhalations have a natural faculty of generation and corruption.*

For that ethereal matter, which is met with abundantly here and there throughout the whole heaven, has a certain promoting power and a natural faculty of generation and corruption, of increase and diminution, of condensation and rarefaction, of gathering and dispersal; and also a natural force both for producing such new, adventitious [adſcititia] bodies of the heaven and for destroying them and bringing them back in turn to their origin, from which they first came forth. In just the same way our earth, by the benefit of the rays of the Sun and of the planets, produces certain meteors, also disperses them again, and finally draws back the matter of which they were composed.

[Margin: Motus alterationis ut circa terram, ſic & circa reliqua corpora ætherea ſuo tamen modo accidit] *The motion of alteration occurs as around the earth, so also around the other ethereal bodies, though in its own way*

Finally, just as this motion of alteration is perpetual in our atmosphere, so too [is it] in the atmospheres of all the other celestial bodies — in each, however, after its own manner. For the things that happen on the earth under an earthly condition happen in Jupiter under a Jovial condition, in Mars under a Martial condition, in the Sun under a solar condition, etc.: that is, whatever takes place on the terrestrial globe (by reason — so that you understand the matter rightly

— of those effluvia), all of it likewise happens in its own way on the other bodies of the world.

[Margin: Haud adeò proclive probatu eſt, ætherea corpora eſſe ſolida, atq́; ex heterogeneis prorsùs conſtare partibus.] *It is not so easy to prove that the ethereal bodies are solid and consist entirely of heterogeneous parts.*

But, you will say, it is indeed asserted with the greatest ease, but demonstrated only with great difficulty, that all the ethereal bodies, each and every one, are solid, opaque, and composed entirely of heterogeneous parts; that they continually emit and throw out effluvia of breaths and vapours, of various kinds and differing quality, now denser, now thinner, both into the atmospheres that the individual celestial globes possess and also beyond them, into the most ample aether; and that these effluvia then, according to their nature, are gathered together, coagulated and condensed in the most diverse ways, and are again separated, thinned and dispersed, etc. For my part I readily grant that nothing is truer than that it is much easier to say than to do, and to speculate than to prove soundly that things really are entirely so in truth — especially concerning things extremely distant and remote, which by no means come within the senses so that they could be distinctly detected.

[Margin: Autor confidit ſe demonſtraturum,dari generationes, alterationesq́ue cœleſtes.] *The author is confident that he will demonstrate that there are celestial generations and alterations.*

However that may be, I have no doubt at all that I shall demonstrate most clearly all those things that we asserted a little before in the case of most of the bodies of the planets; and that in the rest too I shall deduce, by no less sound an inference, that they also are likewise of this kind, and that the same things can happen equally in most of them — if not from some necessity, at least with the highest probability.

[Margin: Deſcriptio Corporis Solaris ex ſententiâ Autoris.] *A description of the body of the Sun, according to the author's opinion.*

Now let us come to the matter itself, and begin with the chief, highest and most eminent celestial globe, the source of light and heat, that admirable work of the Almighty — the Sun, I say. Many believe its body to be most pure, most subtle, most smooth, most polished and most round, thoroughly diaphanous, and most uniform and most constant in its light. Nevertheless we have found by experience, very clearly, that the Sun has its opacity and solidity and consists of heterogeneous parts — namely of solid and liquid — and that its surface is not geometrically even, nor optically polished, but only astronomically spherical, like the billowing sea of the earth, and like the Moon, rugged with mountains and valleys, as Scheiner puts it in the *Rosa Ursina*, Book 4, Part 2, Chapter 11, p. 604 [Roſâ Urſinâ Lib. IV. P. II. Cap. XI. pag. 604]. The Sun is by no means wholly luminous and pure, but has parts that are partly darker and partly brighter; and in it, moreover, a continual succession of changes and a wonderful alternation of rarefaction and condensation are plainly detected. So we are not afraid to say — as we shall also set out clearly later — that no body

exists in the whole world that is subject to so many alterations and vicissitudes as the Sun itself.

[Margin: Nullum Mundanorum corporum majoribus alterationibus & vicisſitudinibus eſt obnoxium, quàm corpus Solare.] *None of the bodies of the world is subject to greater alterations and vicissitudes than the body of the Sun.*

But to reveal our meaning to you still more clearly concerning this immense and truly admirable body of the Sun: know that I, with innumerable eminent learned men, hold firmly that [it] consists, as we have just said, of two especially different parts, namely solid and liquid.

[Margin: Sol conſtat ex partibus ſolidis & liquidis, igneis ſcilicet lucidisſimis.] *The Sun consists of solid and liquid parts — fiery ones, that is, and most luminous.*

The solid parts, however, are not altogether like these earthly ones of ours (except that [it] likewise has its eminences, or mountains, and concavities, or valleys), but by their nature are most luminous and most splendid; nor are its liquid parts in any way comparable with ours. For they are not aqueous or watery, or anything of that kind; rather, it is a most liquid, most thin and most luminous fiery matter, which is enclosed and contained by the more solid matter of that same [body] just mentioned, in just the way that water is by the earthy parts.

[Margin: Materia liquida in Sole eſt verus & realis ignis elementaris.] *The liquid matter in the Sun is true and real elemental fire.*

For the solid solar parts perform in the Sun what the earth [performs] on this terrestrial globe; and likewise the liquid solar parts perform in the Sun what the water [performs] there. I add that this very liquid matter is true elemental fire [ignis elementaris]: not indeed so dreggy, impure and thick as our fire, but much purer, more refined and thinner, needing not even the least nourishment; or, if perhaps it has need of it, it supplies from its bowels, caverns and passages so much nourishment that it can always be kept in vigour — just as our fire-spewing mountains, Vesuvius, Etna, Hekla and others, which have been blazing since the world was founded and are by no means burnt away, perpetually belch out and cast forth sharp and raging flames, and yet are never consumed.

[Margin: Materia liquida illa Solaris nullas fundit flammas, ſedfumos vaporesquè tantum ejicit.] *That liquid solar matter pours out no flames, but casts out only smokes and vapours.*

Further, however much this liquid matter is kept in a perpetual agitation of heat [æſtus], it nevertheless conceives no flames, much less pours them out and darts them forth; but perpetually it only casts out and breathes out smokes and vapours, like boiling water or some very hot liquid. Nevertheless it is true and real fire, and as it is most luminous, so it is also most burning: so much so that in the Sun is found that genuine elemental fire which the Peripatetics have sought until now beneath the concave of the Moon, but in vain.

[Margin: In Sole ignis elementaris quærendus non ſub Lunæ concavo.] *Elemental fire is to be sought in the Sun, not beneath the concave of the Moon.*

For [it was] transferred into the Sun by God, Best and Greatest [D E O O. M.], at the first creation, together with the primordial light — or rather, [it is the fire] out of which the body of the Sun origi- nally was composed — as Kircher rightly holds in the *Itinerarium Exstaticum*, p. 148 [Itinerario Exſtatico pag.148]: *that the Sun is the first fire of corporeal fires, and the true element of fire in this sensible world, the most compacted light of the primeval light and heat, and a most fervent and most burning fire.*

[Margin: Kircheri ſententia de admirando Solis corpore.] *Kircher's opinion on the admirable body of the Sun.*

[Margin: Corporis Solaris plenior deſcriptio.] *A fuller description of the body of the Sun.*

And so this fiery liquid (if one may speak thus) is as it were a most vast ocean of lights and a fiery sea, which has its abysses, hidden channels, gulfs and whirlpools; which, like our sea, is agitated by certain perpetual rollings of waves, and in its own way continually vomits out and exhales evaporations and exhalations — and this the more or the less, according as that matter in its bowels and inmost recesses, that fiery ocean, and its waves are the more or the less moved and stirred up.

[Margin: Ex circumrotatione corporis Sclaris fluxus & refluxus Pelagi illius ignei oritur.] [recte: Solaris] *From the circumrotation of the solar body arises the flux and reflux of that fiery ocean.*

This commotion and agitation, moreover, is all the more vehement, and the forces for thrusting out and throwing off vapours are all the more keenly intensified and roused, because the Sun is engaged in a certain perpetual circumrotation, completing one revolution about its axis in every twenty-seven days or so. From this arises a definite circulation of the fiery solar ocean, and an alternation of flux and reflux; so much so that it is no wonder that the Sun can emit and belch out so many and such great effluvia from this continual and more vehement commotion. From these effluvia, in their own time, when those breaths are condensed and gathered together, so many and such great spots and faculae of the Sun are generated and produced.

[Margin: Prope Solem dari maculas, & faculas varii generis.] *That near the Sun there occur spots, and faculae of various kinds.*

As we have clearly ascertained from observations, such spots quite often occur near the Sun, both fainter ones and more compact, blacker and denser ones; and also faculae of various kinds, little lights [luculas], shadows and mists, now larger, now smaller — indeed some that, compared with the earth, are of unusual size. In these spots and shadows, too, more compact and very dense nuclei are frequently seen; and these, together with the spots themselves, sometimes reach such density and opacity that they allow absolutely no passage to the very light of the Sun, so extremely intense as it is, a light to which nothing whatever in the world is comparable. Moreover, I would have you know that these spots are generated in every part of the Sun, and so also sometimes in

the very middle of the disc, and that there too, shortly afterwards, they are consumed and dispersed again.

[Margin: Mira macularum facularumq́; Solarium mutatio, atq́; vicisſitudo.] *The wonderful change and vicissitude of the solar spots and faculae.*

Not rarely, too, they undergo wonderful changes: now very dense spots are born from very faint shadows and faculae; now these in turn are transmuted and resolved into shadows and faculae. So a continual vicissitude, generation, alteration and corruption of these things — whenever, that is, such matter is supplied — plainly appears and is observed not far from the Sun itself (since no parallax is ever detected in them).

[Margin: Maculæ Solares ex effluviis & evaporationibus Solis promanant.] *The solar spots flow forth from the effluvia and evaporations of the Sun.*

This matter, now, is that very evaporation and exhalation (since it can by no means arise from anywhere else) which, as was shown above, is breathed out and exhaled from the very body of the Sun; and these consist entirely of diverse heterogeneous parts, having definite degrees of opacity and density — now of thinner, now of more opaque, now of drier, now of more viscous, glutinous (to speak in our customary way) or bituminous ones. From this, too, diverse phenomena are produced: from the thinner, purer and drier [parts], namely, shadows, faculae and little lights; but from those impurer, coarser, viscous [ones], spots, and of these same the nuclei are engendered.

[Margin: Solem ſuam habere atmoſphæram, in quâ alterationes etiam noſtris frequentiores accidunt, luculenter deducitur.] *It is clearly deduced that the Sun has its own atmosphere, in which alterations occur even more frequent than ours.*

Since, then, the exhalations of the Sun are heterogeneous parts of this kind, why should not that very body which ejects them also consist of diverse heterogeneous parts, as was asserted at length in the preceding [pages]? Moreover, we see such admirable and most manifest generations, changes, alterations, condensations, rarefactions, comings-together and separations — indeed local motions of bodies, and of the things and materials ejected and evaporated from the Sun itself — carried out almost continuously, like the clouds and sublunary meteors that flow forth from the earth. Since we see this, is it not clearly proved from it that the Sun has its own atmosphere, and that in it, according to the character of its power, there occur generations and corruptions not unlike [those of] sublunary things, and rarer [?] — indeed, that sometimes far more frequent and more remarkable ones occur there (especially if you examine exactly the observations of the spots made by Scheiner and by us) than can ever [occur] near this earth?

[Margin: Aliis rationib⁹ probatur dari atmoſphæram circa Solem.] *By other reasons it is proved that there is an atmosphere around the Sun.*

Although these [arguments] would suffice, so that no further proofs would be needed as regards the Sun, it can nevertheless be deduced without difficulty from still other reasons and observations that there is an atmosphere, and that

in it that matter of the aether is not always equally thin, but alterable — and indeed sometimes much denser and coarser.

[Margin: Sol quandoq́; exutus prorsùs radiis cœlo etiam ſereno conſpectus eſt.] *The Sun has sometimes been seen altogether stripped of its rays, even with a clear sky.*

Above all, [it is deduced] from those phenomena that have occurred around the Sun, when the Sun, over a space of several days, and indeed in different places, appeared now paler than usual, now ruddier, indeed altogether stripped of its rays, although the sky was quite clear, so that even the stars shone out clearly by day, and indeed at noon. 1. In the time of the Emperor Justinian, as Patricius [Francesco Patrizi] reports from Petrus Messia [Pedro Mexía], *Pancosmia*, Book 19, p. 111 [Lib. XIX. Pancoſm. pag. 111]: *for the greater part of the year, with the air clear and veiled by no cloud, the Sun shone so feebly that its light scarcely exceeded the brightness of the Moon.* 2. As Paulus Diaconus notes, the Sun was darkened in the year 790, and for 17 days did not give its rays. 3. On the testimony of Pliny the Elder, the Sun was pale for a whole year after Caesar the Dictator was killed. Tertullian writes that something similar happened in the time of Augustus, and Kircher reports that it was also observed in 1652.

[Margin: Sol adeò obtuſo lumine eſt obſervatus ut etiam Stellæ in meridie conſpectæ fuerint.] *The Sun has been observed with so dulled a light that even the stars were seen at midday.*

4. In 1547 Gemma Frisius and Cornelius, [his] son [Cornelius Filius], observed that for three days the Sun appeared as if suffused with blood, but most of all toward sunset, so that even most of the stars were seen at midday. Josephus Scaliger [Joseph Justus Scaliger], as a boy of 7 years, also saw the same phenomenon, from April 22 for four whole days, as he himself testifies in the *De emendatione temporum*, Book 5, on the year of the murder of Caesar [de anno, cædis Cæſaris]; and it was noticed not only throughout the Low Countries [Belgio], but likewise by others in France, Germany and Britain.

[Margin: Sol inſtar ferri candentis apparuit Cæſariopoli.] *At Caesareopolis the Sun appeared like glowing iron.*

5. David Frölichius [David Frölich] observed a phenomenon of this kind at Caesareopolis [Kežmarok], as is clear from his letter written to me in the year 1645: "I myself," he says, "on April 25, New Style [25 April. ſt. n.], at 3^h in the afternoon [hor. 3 veſpertinâ], saw the body of the Sun like glowing iron, or a tawny Moon, altogether deprived of its rays." Far more examples of this, too, are met with in the histories.

[Margin: Cauſſa pallidi & obtuſi luminis iſtius Solaris, nonniſi in atmoſphæram ejus referenda eſt.] *The cause of that pale and dulled solar light is to be referred to nothing but its atmosphere.*

If, now, we inquire into the cause of the overshadowing and obscuring, or of the pale and dulled light, of the Sun, it can by no means be drawn from our sublunary air, or from earthly vapours and exhalations, still less from clouds;

it will surely have to be sought elsewhere. For if that interposed matter had been in our atmosphere — believe me — those phenomena would neither have lasted so long, nor have been so univer- sal that they were observed in exactly the same way throughout different regions (as indeed happened above all in 1547) — to say nothing of the fact that the Sun alone, by itself, could by no means have appeared ruddier and paler than usual, since at that time the sky was very clear on all sides, so that even the stars sparkled at midday.

[Margin: In Sole nonnunquam ſævæ & inſolitæ tempeſtates & inundationes oriuntur.] *In the Sun fierce and unusual storms and floods sometimes arise.*

Since this is so, that genuine cause must therefore be searched for nowhere but in the aether itself — and indeed in the very atmosphere of the Sun. And so I fully believe that at that time fierce storms and unusual floods arose in the Sun (for it is not absurd that [it] too sometimes suffers its own paroxysms and its own vicissitudes), and that it then poured out and emitted a great quantity of vapours and smokes into its atmosphere or vortex [verticem]. These expirations, once they had spread out and condensed to such a degree, like a huge, thinner spot or very dark clouds, that they overshadowed the whole Sun entirely, in part [?] [ex parte], and in a way closed off the path to its rays, [the Sun] necessarily appeared bare of rays and altogether despoiled.

[Margin: Quâ ratione Sol pallidior, obtuſior,&rubicundior appareat.] *How the Sun comes to appear paler, duller and ruddier.*

From this it came about that the Sun, at this time or that (in proportion to the greater and lesser density and diversity of that nature), was seen now paler and duller, now ruddier and darker. Kepler, a man of penetrating intellect, also had an inkling of this long ago, as one can read in the *Astronomiae pars optica* [Aſtronomiæ parte Opticâ], Chapter 6, no. 11, p. 259 [Cap. VI. n. 11. pag. 259]; and likewise in the book *De stella nova in pede Serpentarii* [Libro de novâ Stellâ, in pede Serpentarii], Chapter 23 [Cap. XXIII], where indeed he deduces that the matter of the heavens is alterable, and that the [matter] which dulled the light of the Sun, but by no means that of the stars, had settled neither in our vaporous air, nor below the Moon, nor near it, but in the highest aether. For he says: *It is therefore to be sought in the deep aether, very close to the Sun, between it and the earth; indeed, offered to us from there, it is to be embraced as an argument for the mutable ethereal matter which is poured, liquid, around the stars.* But we must not dwell on these things any longer; let us turn to the Moon.

[Margin: Corporis Lunaris deſcriptio : quod ſit opacũ, aſperum; atq; ex partibus ſolidis & liquidis conſtet.] *A description of the body of the Moon: that it is opaque and rough, and consists of solid and liquid parts.*

That the body of the Moon is most opaque, rough, rugged, full of mountains and valleys; that by its opacity it denies passage to the light of the stars, indeed of the Sun itself; that it consists of most diverse parts, earthy as it were (but according to its own nature) and watery — solid and liquid: mainland, seas, lakes and marshes, islands and promontories; and that its matter, moreover, is not altogether uniform but extremely diverse, as all can gather from those various

colours met with here and there on its surface — this, I think, is now hidden from almost no one in the learned world any longer, and no one can deny it. It has been discovered more than enough in our age, and also demonstrated abundantly to the eye of the whole world, in Chapter 8 and especially Chapter 13 of the *Selenographia* [Cap. VIII. & imprimis Cap. XIII. Selenographiæ].

[Margin: An Luna etiam habeat ſuam atmoſphæram ?] *Does the Moon too have its own atmosphere?*

So it is not pertinent to say more about these things here; it remains only to investigate whether the Moon, like our earth and the body of the Sun, likewise enjoys an atmosphere of its own, into which it exhales and breathes out evaporations and exhalations no less [than they], though in its own way; and then, in which, according to the faculty implanted in it, similar alterations, condensations and rarefactions take place.

First of all, I do not deny that this very thing is harder to demonstrate in the Moon than in the Sun itself, since such manifest and detectable observations are entirely lacking, and those changes near the Moon are not so sen- sible, nor do they come so frequently into everyone's view, as [they do] near the Sun.

[Margin: Evaporationes Lunares haud adeò facilè quàm Solares deprehenduntur.] *Lunar evaporations are not detected as easily as solar ones.*

Nevertheless, it is not contrary to reason that there too, to some extent, effluvia and certain expirations occur. For the Moon is composed of purely heterogeneous parts, of diverse opacity; its surface is filled with various lakes, marshes and seas, surrounded on all sides by fairly high mountains, not altogether unlike ours; and besides, because of its nearness, it is most exposed to the rays and forces of the Sun and of the other planets. I consider, however, that these lunar evaporations themselves are far thinner and purer than the solar and terrestrial ones, so that it is very difficult for anyone to detect them, whether with the naked eye or with an eye armed with even an excellent tube.

[Margin: Singulare phænomenum in Lunâ ab Autore deprehenſum.] *A singular phenomenon detected in the Moon by the author.*

Yet on separate occasions I have found by experience that the Moon and its spots did not appear to me equally bright, clear and transparent at all times — even when the sky was clear on all sides, so that I could make out little stars of the sixth and seventh magnitude, with the Moon at the same altitude and the same elongation from the earth, and moreover with one and the same excellent telescope. Rather, at one time and another they were seen far brighter, clearer and purer (a thing which, as new and unusual, I have certainly wondered at not a little, and quite often).

[Margin: Dari circa Lunam alterabilem materiam vaporoſam.] *That there is alterable, vaporous matter around the Moon.*

Here I ask: what is the reason for this phenomenon? Truly, however much we weigh the matter, we can assign no other, truer cause than that around the Moon itself there is some alterable matter — now thicker, rarer, now denser and thinner — like clouds and very thin shadows, which, although they sometimes

fill our air, still do not altogether hide the stars, but only show them somewhat more nebulous; or like very subtle shadows and the subtler matter of the solar spots, which not infrequently veils the Sun in some way in this or that part, so that its colour appears paler or gloomier there.

[Margin: Materiam Cœli quandoque eſſe ſubtiliorem.] *That the matter of the heavens is sometimes subtler.*

This matter, I say, renders the lunar spots and the Moon itself, at different times, according to the constitution of the evaporated matter, now somewhat gloomier and paler, now clearer and brighter.

[Margin: Vaporoſus Orbis circa Lunam aliis obſervationibus & rationibus probatur.] *A vaporous orb around the Moon is proved by other observations and reasons.*

But it can be proved still more evidently, from certain total eclipses of the Sun that have been observed, that exhalations and a certain vaporous, alterable matter are sometimes found around the Moon. Kepler did this at sufficient length and admirably in the little book *De stella nova Serpentarii* [libello de novâ Stellâ Serpentarii], Chapter 23, p. 115 [Cap. XXIII. pag.115], from the eclipse of the Sun observed at Naples and Antwerp in the month of October, in the year 1605. At that time, when the whole Sun was covered by the Moon, a red and flaming redness of equal breadth on all sides, which had occupied a good part of the sky, was detected all round the periphery of the Moon; so that, for this cause and by reason of this brightness, no stars at all could then be seen in the whole Kingdom of Naples, although the whole Sun was entirely covered by the Moon (for the diameter of the Moon exceeded the size of the solar diameter).

[Margin: Tempore Eclipſeos Solaris nonnunquam Stellæ clarè affulgent.] *At the time of a solar eclipse the stars sometimes shine brightly.*

Whereas at another time total eclipses have brought on astonishing darkness, so much so that even the stars met the eye in abundance. Such was the [eclipse] of 1560 August 12, which Clavius recorded, and several other eclipses, which Kepler mentions in the *Astronomiae pars optica* [Aſtron. Parte Optic.], Chapter 8, no. 2, p. 292 and following [Cap. VIII. n. 2. pag. 292 & ſeq.]. With these and other examples and reasons, on pp. 115, 117 and 118 of *De stella nova Serpentarii* [de Stellâ novâ Serpentarii], he concludes: this cir- cle and the brightness surrounding the Sun were nothing but solar rays refracted in a certain denser matter very close to the Moon, by means of which that glare and brightness was carried to our eyes. This, however, could by no means have happened if no other matter, thicker than the aether, had surrounded the Moon. For the said author presses the point in these words: *The matter by which this brightness of the Sun was received must by no means have been lower than the Moon, but poured around either the Moon or the Sun itself, or at any rate poured in between both luminaries, and so in the aether.* Likewise on p. 119: *Therefore it was not the air poured over us, but some loftier and wholly celestial matter, that cast this brightness, received from the Sun, around the Moon.*

[Margin: Circa Novilunium juxta Solem Luna obſervata eſt.] *Around the new moon, the Moon was observed beside the Sun.*

That such somewhat thick lunar and solar matter sometimes clings in the neighbourhood of both luminaries, and there gradually becomes more and more consolidated and attenuated, indeed is entirely dispersed again, is detected no less from a certain observation made at Seville [Hiſpali]. For in the year 1553, in the month of February, around the new moon, the Moon was seen by the whole city standing beside the Sun at noon itself. From this phenomenon, in turn, together with the frequently cited author Kepler, we conclude *that the matter of the heavens, since at different times it is of a different subtlety, differing greatly from itself, also sometimes absorbs more brightness than at other times; and so it blinds men's eyes now more, now less, in seeing stars by day* (*De stella nova Serpentarii* [Libell. de novâ Stellâ Serp.], Chapter 23, p. 120 [Cap. XXIII. pag. 120]).

[Margin: Argumentum pro Atmoſphærâ Lunæ.] *An argument for the atmosphere of the Moon.*

For the rest, that vaporous orb around the Moon is established by a still more solid argument: in certain total eclipses of the Moon a certain small portion, brighter than the remaining, darkened part of the Moon, is clearly detected, like little lights [luculæ] and faculae — not, indeed, remaining long in the same place, but mobile and variable. Whereas, however, no light at all of its own inheres in the Moon, but it draws all that it has entirely from the Sun. This is shown both by its phases [and] the solar eclipses, and by the total eclipses of the Moon at times — namely, when the Moon is so covered and darkened by the earth's shadow that it can scarcely, or not even scarcely, be made out in the sky, even by those skilled in astronomy, as we said at length in Chapter 6, p. 116 of the *Selenographia* [Cap. VI. pag. 116 Selenographiæ].

[Margin: Notabilis Eclipſis Lunaris, in quâ luculæ diverſæ apparebant.] *A notable lunar eclipse, in which various little lights appeared.*

Among the most notable eclipses of this kind, however, the one that presents itself above all is the one that I myself happened to observe in the year 1642, on April 15/25. In it, at the time of greatest obscuration, although the air was clear on all sides, so that even the smaller little stars were seen perfectly well by everyone, the whole Moon nevertheless vanished altogether, so that scarcely, at intervals, some very tiny little lights here and there on the lunar body came into view. Again, at other times, when likewise it can in no way be illuminated by the Sun, it nevertheless pours out some light — as usually happens at the time of new moon in the fresh and horned phases, and also in certain total eclipses.

The first, as we deduced at length in the same Chapter 6 of the *Selenographia* [Capite VI Selenog.], is that light reflected from the earth. The other, however — which shows itself scattered, like a little light, in the Moon when it is entirely darkened, and indeed always about the limb farther from the ecliptic — takes its origin from nothing but the atmosphere itself, or the lunar vaporous orb, in which the solar rays, as in some denser medium (just as happens to the same

rays in our twilight air, so that for that reason it must grow light and become day a little sooner than could otherwise happen) are refracted and projected onto the Moon. In this way certain small parts of the Moon are illuminated here and there, and are seen like little lights or faculae.

[Margin: Inſigne phænomenon in deliquio Lunari 1635 detectum, pro ſtabiliendâ atmoſphærâ Lunæ.] *A remarkable phenomenon detected in a lunar eclipse in 1635, for establishing the atmosphere of the Moon.*

This has likewise been noted several times in the eclipsed Moon, above all in the year 1635, on March 3, and again on August 27 of the same year, in those total eclipses. For in the former [eclipse], which then had a southern latitude, a notable glare was detected — not, indeed, always fixed in the same place, but variable; yet in such a way that it always remained about the southern limb. In the other eclipse, however, which was at that time in southern latitude, they observed an almost similar phenomenon, but in the northern part of the limb. This light can by no means arise from anywhere else than from the fact that the solar rays are refracted in the vaporous orb poured around the Moon (which is perhaps so ample that it far exceeds even our twilight atmosphere).

[Margin: Atmoſphæra Lunæ tam noſtrã atmoſphæram crepuſculinam, quàm umbram terrenam vaſtitate vincit.] *The atmosphere of the Moon surpasses in vastness both our twilight atmosphere and the earth's shadow.*

And although the Moon is in the very middle of the shadow, nevertheless in that atmosphere of the Moon, which is greater than the earth's shadow, the solar rays are always received in such a way that they must always pass through obliquely, and so refracted — and indeed towards the Moon. By means of these refracted rays a small portion of the Moon is illuminated here and there, according to the different refraction, or the various degrees of density of that matter.

[Margin: Quâ ratione luculæ in Eclipſes Lunares inducantur.] *How the little lights are brought into lunar eclipses.*

Moreover, since the Moon, by its proper motion, together with its vaporous orb, continually advances according to the order of the signs, this glare too, therefore, does not always remain in the same place, but migrates into one [place] after another. [This is] because the Sun with its rays strikes successively one part of the vaporous orb after another, and in this way refracts the rays now one way, now another — namely to the perpendicular, towards the Moon — so that these little lights can in no way be long-lasting, but continually variable: as this very thing could be demonstrated more clearly by a certain diagram, if we wished to dwell on these matters longer; but I judge that we must hurry on.

[Margin: Ex Deliquiis Solaribus infertur, dari Atmoſphæram Lunarem.] *From solar eclipses it is inferred that there is a lunar atmosphere.*

And that all this is so, partial eclipses of the Sun also show. For as I weighed this matter somewhat more closely, it came to my mind that in some eclipses I had detected an unusual fluctuation of the lunar limb, whereas around the solar limb nothing, or very little indeed, of that trepidation was perceived. This,

truly, I have nowhere else to refer than to [the fact] that there is a definite atmosphere around the Moon, in which matter, now thinner, now denser, is met with, which is subject to condensation, rarefaction and alteration. Through this matter, therefore, which refracts the lunar rays in various ways, we see the limb of the Moon sometimes trembling and fluctuating.

[Margin: In EclipſiSolari anno 1618, limbus Lunæ valdè fluctuabat.] *In the solar eclipse of the year 1618 the limb of the Moon fluctuated greatly.*

A certain eminent mathematician was likewise led to this opinion when he observed an almost similar phenomenon around the limb of the Moon at Barcelona [Barcinone], in the year 1628, on December 25, in a solar eclipse — as one may read in Scheiner, *Rosa Ursina*, Book 4, Part 2, Chapter 27, fol. 740 [Lib. IV. Part. I I. Cap. 27. fol. 740.]: *I observed* (says that mathematician, whose name Scheiner keeps silent) *in the same eclipse a thing to be wondered at in the Moon placed beneath the Sun: namely, the periphery of the Moon fluctuated and trembled very greatly, the periphery of the Sun trembling either not at all or very little, no differently than a sea agitated by waves, with wave driving wave. From this I concluded that the sphere of the Moon is surrounded by a certain atmosphere no smaller, and perhaps thicker, than the earth is [surrounded]. Let the Reverend Father see whether I have rightly con- cluded. Certainly I find no other cause why, at the same altitude of the Sun, the periphery of the Moon always trembled much more than the periphery of the Sun, except this: that the solar rays had been cut off by the vapours surrounding the Moon.* He adds: *From this a greater light seems to arise for the solar spots and the comets, if, as from the globe of the earth and of the Moon, so also from the globes of the remaining planets vapours are breathed out.*

[Margin: DeLunæ atmoſphærâ Scheineri & Kircheri judicium.] *The judgment of Scheiner and Kircher on the atmosphere of the Moon.*

These are his words. But what Scheiner, a man endowed with a truly polished judgment, thought on this matter can be seen clearly on the same cited page; for he says: *That learned mathematician, a most exact observer, wrote these things to Rome in the year 1629, on January 12. What fallacy there is in his acute reasoning, astronomers have not yet discovered.* Kircher reports something similar in his *Ars magna lucis et umbrae* [arte ſuâ magnâ Lucis & umbræ], Book 1, Chapter 3, p. 13 [Lib. I. Cap. III. pag. 13.]: namely, that Father Cysat (unless he himself, since he was staying at Barcelona at the same time, is the mathematician whose name Scheiner passed over in silence) detected in the same eclipse an orb of vapours and exhalations around the Moon; he adds moreover: *I do not doubt that the same happens in the remaining globes of the planets, which, just as [they have] centres different from the centre of the universe, so also constitute different spheres of exhalations.*

[Margin: Cyſatus circa Lunam Orbem vaporoſum deprehendit.] *Cysat detects a vaporous orb around the Moon.*

Cysat wrote almost this very thing, but in other words, from Barcelona to Father Juan Eusebio Nieremberg [Pat. Joh. Euſebium Nierembergium] in the year 1628, as is evident from his *Historia naturae* [Hiſtoriâ Naturæ], Book 2,

Chapter 11 [Lib.II. Cap. XI.]; [his words] truly deserve to be attached here: *And indeed in the recent solar eclipse, which fell on the very day of Christ's Nativity, I clearly observed in the Moon, opposite the Sun, something that strongly proves the very point that the comets and the solar spots also press, namely that the heaven is not exempt from the thinness and the variations of the air. For I noticed that around the Moon there is a sphere, or a certain vaporous orb, no differently than around the earth, so that, just as vapours and exhalations are breathed out from the earth up to some sphere, so too in the Moon. If Your Reverence had been with me and had inspected the Moon under the Sun, I would have demonstrated to Your Reverence what I say, both by reason and to the eye; now I, for my part, know it.* Thus far Cysat. This is also most true; and from it — especially from all the things brought forward above — it is rightly concluded that vaporous orbs exist around the remaining planets no less than around the Sun and the Moon.

[Margin: Quinam inter Autores huic ſententiæ de Lunæ atmoſphærâ ſubſcribant.] *Which authors subscribe to this opinion on the atmosphere of the Moon.*

Not a few of the most distinguished men, too, defend this atmosphere of the Moon together with us: as Plutarch, in the book *De facie Lunae* [lib. de facie Lunæ], Chapter 45; Mästlin; Kepler, in the preface to the *Ephemerides*, p. 9, the *Epitome Astronomiae* [Epit. Aſtron.], Book 1, p. 57, likewise Book 3, p. 893, and the book *De stella nova Serpentarii* [Lib. de novâ Stellâ Serp.], Chapter 23 [Cap. XXIII.]; David Fabricius, in the Prognostication [Prognoſt.] for the year 1626; Giordano Bruno [Jordanus Bruno], in the book *De immenso* [Lib. de immenſo]; Longomontanus [Longomont.], Book 1 of the *Theoricae* [Lib.Theor.I.], Chapter 4; Marius Bettinus [Mario Bettini], Apiar. 8, Prog. 2, prop. 10 [Apiar.VIII.Prog.2.prop.10.]; Antonius Maria de Rheitâ [Anton Maria Schyrleus de Rheita], Book 4, Chapter 2, Member 10 of the *Radius Syderomysticus* [Lib.IV. Cap. 2. Memb.10. Radii Syderomyſtici]. For he says: *since the new astronomical spyglass, excellent and very long, show its body to be solid, and also most plainly surrounded by its own atmosphere, just as our earth is, or by vapid air [vapido aëre], I truly do not see by what reasoning we should deny it the other elements.* Wendelen asserts the same in the preface to the *Eclipses lunares* [præf. Eclipſium Lunar.], p. 5: *The earth* (he says) *is surrounded by its own air, and the Moon likewise by its own, perhaps no purer than this of ours.* Above all, however, Mästlin, a man of the sharpest intellect, testifies in these words, in a certain little book of theses published at Tübingen in the year 1606, that alterations occur in the Moon, indeed that he had seen rains in the Moon: *In the lunar eclipse on the evening of Palm Sunday in the ye- ar 1605, a certain blackish spot was seen in the body of the Moon, towards the north, darker than all the rest of the body, which presented the shape of red-hot iron. You would have said they were clouds spread over a large region, heavy with rainy and stormy showers, of the kind that one not rarely sees [moving] from the ridges of the higher mountains down into the lower places of the valleys.*

[Margin: Mirum phænomenum in Lunâ conſpectum.] *A remarkable phenomenon seen in the Moon.*

And do not think, says Kepler, *that it was one of the old spots: Mästlin himself showed me the diagram the year before. The spot differed both in position and in size: for it occupied about a fourth or a fifth part of the lunar surface, and was, besides, so black that it stood out even in the darkened Moon.* Johannes Phocylides [Johannes Phocylides Holwarda] adds, moreover, on p. 268 of *De novis stellis* [de novis Stellis]: *Although this was a certain extraordinary fumigation of evaporating exhalations, certainly greater than usual, it nevertheless shows us clearly how much she [the Moon], like the other planets too, smokes when struck by the solar ray, and breathes herself out into the neighbouring aether.*

Lastly, you will understand clearly what the excellent Boulliau decides on this matter from his letter to me, dated at Paris [Lutetiæ] on 1662 August 3. I have chosen to append it in this place for this reason: because it brings no small light and weight to this question, namely that lunar exhalations and evaporations exist.

[Margin: Literæ Celeb. Bullialdi ad Autorem.] *The letter of the celebrated Boulliau to the author.*

Most honoured Sir: in my last letters I sent you old astronomical notes; but it slipped my memory then to add at the same time an observation I made concerning the Moon, which, if still others are added to it, seems sufficient to prove that vapours emitted by that planet spread around its body. This observation, which I send to You, was made carefully by me, and with the greatest attention of eyes and mind; I set myself against every preconceived opinion, and avoided the deceptions by which our air could have drawn me into error. Receive, then, the very words that I wrote at that time in the papers of my observations.

[Margin: Inſignis obſervatio Bullialdi; dari vapores circaLunam.] *A notable observation of Boulliau's: that vapours exist around the Moon.*

In the year 1659, on Thursday [die Jovis], March 27, at about 8^h *after noon, I examined the Moon with a spyglass or optical tube. It was moving towards the rays of the Sun [ad Stell. radios Solis] [?], and occupied,* n. *[?], about 2° of Gemini. The sky was very clear and purified, and through the tube the smallest stars could be seen, which cannot be discerned with the naked eyes. In the part of the Moon that receives light from the earth and shines by it, I noted dense mists, so that part of the eastern disc was seen only with the greatest difficulty, the northern part [pars v. Borea] [?] a little more clearly; but the southern part, although it too was surrounded by mists, appeared clearer and brighter than the rest.*

[Margin: Nebulæ Lunares.] *Lunar mists.*

We cannot say and determine that those mists hung in our air that surrounds the earth, for they would have taken away the sight of the stars of the third and fourth magnitude. Those vapours must therefore have been emitted from the very body of the Moon. I noted again, for a short space of time, that the Moon was surrounded by those vapours, shining with a tawny and golden colour, with which coronae do not usually shine. This phenomenon [was] seen at Paris.

I remember that you told me something similar had been observed by you when I was staying as a guest in your house. From these twin observations, and from others to be made hereafter, it will be established that vapours and exhalations are emitted from the lunar body, and from the terrestrial one, and spread around its surface. From this, much profit will flow over to physics and optics. Very many authors agree with this opinion; so that time may be spared, I gladly refrain from listing them here.

[Margin: An circa reliquos Planetas etiam detur Orbis vaporoſus.] *Whether there is a vaporous orb around the other planets too.*

From here I now turn to inquiring whether around the other planets too, the superior as well as the inferior, there exists a vaporous sphere, as there does around the Sun and the Moon. Indeed, just as all the bodies, wandering and fixed alike, agree entirely with the Sun, the Moon and the Earth in this, that they likewise are not perfectly spherical, not at all smooth, but extremely full of hollows, uneven, rough and broken, and also of differing density and opacity (as is sufficiently admitted from the overall light they cast to us, and as we set out to prove clearly in Chapter 6, p. 133 of the *Selenographia*), and especially since they display very diverse colours, and various spots and shadows, and changeable ones at that, as anyone can readily see in Jupiter: it is certainly necessary that the other planets, too, no less consist of purely heterogeneous parts, and are mixed bodies, of the same nature as the Sun, the Moon and our earth; or, what is the same, that they are necessarily subject to generation and corruption, as to their exterior parts only, I say; and consequently that they also breathe out and cast forth expirations, vapours and the effluvia of breaths.

[Margin: Planetæ omnes conſtãt ex partibus heterogeneis,ac generationi&corruptioni,quoad partes, ſunt obnoxii.] *All the planets consist of heterogeneous parts, and are subject to generation and corruption as to their parts.*

There is the further point that all the bodies of the world, together with the Sun and the Moon, dwell in one and the same medium, namely the aether, which is endowed everywhere with the same transparency, subtlety and essence, as has already been said several times. Because of this it is altogether necessary that generations and corruptions also occur around all the aethereal bodies.

But, you will say, why are alterations and changes of this kind not equally evident and detectable in those smaller planets and in the fixed stars, as they are in each of the two greater luminaries [in utroq; luminare majori]? Plainly because the excessive distance of those bodies from the earth, the smallness of their apparent diameters and the weakness of our sight (even if it is helped by any telescope, however excellent) do not allow us to reach the point at which we could see all those things, and any of the smallest alterations, however much they may occur there, and detect them distinctly.

[Margin: Cur non æq́; in reliquis Planetis ac in Sole &Lunâ alterationes cuivis ſint obviæ.] *Why alterations are not as plain to anyone in the other planets as in the Sun and the Moon.*

What, I ask, do you think? If it were permitted to contemplate our earth from the fixed stars, or even only from the Moon, as the body nearest to us of

all the aethereal ones, an earth on which so many and such great generations, corruptions and transmutations occur daily, do you suppose that we could then detect all of them, each and every one, distinctly? Not at all, certainly; indeed hardly anything more would come into our view from the earth than [does] in the other bodies. Except that to us, dwelling on the Moon, or to the Selenites, only various spots and shadows would be seen around the earth (which would appear under a notable diameter of almost two degrees). These, no differently from the solar ones, would not rarely be seen to be generated there, namely in the earthly atmosphere, and to be altered, increased, diminished, and in their time, in turn, dispersed and destroyed.

[Margin: In Terrâ ex Lunâ conſpectâ pariter ut in Sole maculæ & umbræ obſervantur.] *In the Earth seen from the Moon, spots and shadows are observed just as in the Sun.*

This, however, with an express distinction: since the earth revolves entirely about its axis continually in the space of twenty-four hours, but the Sun only in each period of twenty-seven days, the terrestrial spots would from this be observed to go out completely, as it were, from the earth's disc in the space of twelve hours; whereas this usually happens to the larger and more solid spots of the Sun after an interval of 12 or 13 days.

[Margin: Maculæ Terreſtres ſæpiùs diſcum Terræ peragrare videntur.] *The terrestrial spots appear to travel across the Earth's disc more often.*

But again, just as these solar [spots] very rarely return, that is, only very seldom rise again on the Sun after twelve or thirteen days have elapsed, and its disc a second time, let alone a third, travel across; so those terrestrial spots (namely our clouds, vapours and exhalations) would very often present themselves afresh on the following day, almost in the same place where they had stood on the day before, especially if certain denser and thicker clouds were lingering over some particular horizon. Indeed, they would be visible on as many occasions and days as those clouds stayed unmoved here with us.

[Margin: Vicisſitudines Macularum Terreſtrium ex Lunâ conſpectarum.] *Vicissitudes of the terrestrial spots seen from the Moon.*

Moreover, these clouds of ours, just like the solar spots, would be transformed, condensed and dispersed in various ways. They would differ, however, in this: these terrestrial spots would not be continually visible to the Selenites, even if they were really there, because the earth, with respect to the Moon, continually shows phases that wax alike and wane alike, so that spots lying in the dark part of the earth would in no way be seen. But these vicissitudes would be noted best of all at the time of the opposition of the Sun and the earth, that is, at the time of Full Earth [Pleniterrei], when the whole disc of the earth is fully illuminated.

But if it fell to us to view these spots from the Sun, believe me, they would come into view every day for as long as they lasted; on this condition, however, that at all times they would appear whitish and shining white, as if they were

the brightest faculae, just as the solar spots for the most part [appear] blackish and darker.

[Margin: Maculæ terreſtres ex Sole viſæ ſemper albicantcs & lucidisſimæ apparent.] *Terrestrial spots seen from the Sun always appear whitish and very bright.*

The reason is this: these terrestrial spots, with respect to one standing on the Sun, are steeped in the Sun's light on the side turned towards it, so that they must necessarily appear very bright and whitish. The solar spots, by contrast, being opaque bodies, are always illuminated on the side turned away from us, and only the dark part of the spots, the part turned away from the Sun, falls under our sight. Hence these [solar spots] appear blackish and dark, but those [terrestrial ones] shining white and bright.

Next, it would be a pleasant sight that in some parts of the earth, namely in Egypt and Arabia, on the shores of both Indies, and in other [places] where it rains very seldom, spots would also be generated only very rarely; whereas in other districts of the earth, such as Europe and more northerly places, [they would be generated] extremely often.

Lastly, the solar spots constantly keep to a certain zodiac, as it were, of about 50 and 60 degrees, namely around the middle of the two poles, in which the generations of the principal spots take place; but the terrestrial spots would always be more frequent in the temperate zones, towards either pole, than under the equator, that is, in the torrid zone, since in these regions the air is at all times far purer than in those. Very many other things of this kind would meet our eyes if we were on the Moon and on the Sun, and it would be easy to add them here as well, if we wished to go further; but so as not to seem to digress too far from our aim, let us return to our purpose.

[Margin: Quâ in Terræ parte frequentiores darentur maculæ, ſi ex Sole, vel Lunâ obſervarentur.] *In what part of the Earth spots would be more frequent, if they were observed from the Sun or the Moon.*

These terrestrial generations and changes alone, I say, are what we would detect, and that only from the Moon; for from the other aethereal bodies not even these, nor anything of this kind, could be noticed in any way. For the apparent diameter of the earth, viewed from Saturn, Jupiter, Mars, Venus and Mercury as well as from the Sun, would be of very small size, even though these bodies are at their nearest distance, as is plain to anyone from the little table attached, with Kepler's distances of the planets taken as given.

[Margin: Præter Macularum phænomena nihil in terrâ, ex Sole &Lunâ deprehendi poteſt; ex reliquis verò Planetis penitùs nihil.] *Apart from the phenomena of the spots, nothing on the earth can be detected from the Sun and the Moon; but from the other planets, nothing at all.*

Apparent diameter of the Earth, seen from	Deg.	′	″	‴
the Moon	2	7	22	0
Venus		7	58	34
Mars		5	32	8

Apparent diameter of the Earth, seen from	Deg.	′	″	‴
Mercury		3	56	8
the Sun		2	3	16
Jupiter			50	48
Saturn			15	20

546

[Margin: Quanta foret diameter apparens terræ ex Planetis conſpecta.] *How great the apparent diameter of the earth would be, seen from the planets.*

Therefore the Earth, seen from Venus, appears only twice as large as Venus herself at perigee; from Mars, scarcely a little larger than Venus at perigee; from Mercury, smaller still than Venus; from Jupiter, almost equal to Jupiter; and from Saturn it would show roughly the size of Spica or Arcturus, provided, that is, that the true diameters of the planets and of the fixed stars are taken into account.

Since, then, it is certain that the earth, seen from the other planets (if you except the Moon), would appear very small, so that these generations, changes and corruptions, which occur in abundance both around and on the earth, could in no way be detected, why then do you wonder, candid reader, that changes and vicissitudes of this kind in the other planets, or in the fixed stars, are so imperceptible?

[Margin: Sicut ex cæteris Planetis generationes & vicisſitudines terreſtres,ſic pariter ex terrâ eædem nullo prorsùs modo percipiuntur.] *As with the terrestrial generations and vicissitudes seen from the other planets, so likewise from the earth the same are perceived in no way at all.*

Nevertheless, let us show clearly that around Jupiter itself too, so far removed from the earth, there exists a vaporous sphere, and continual exhalations that can be plainly noticed. And first, I think hardly anyone is any longer unaware that four companions around Jupiter were discovered by Galileo the Lincean [à Lynceo Galilæo], namely those Medicean stars. Each of them performs its own particular motion around Jupiter as its centre, in its own orbit, and completes it in a fixed period.

[Margin: De atmoſphærâ Jovis, ejusq́; Comitibus.] *On the atmosphere of Jupiter and its companions.*

Hence it happens that they are now more, now less distant from Jupiter, namely along a straight line on either side [of it]; and indeed that at their farther remove from Jupiter they appear much smaller than at the nearer one, that is, when they are closest to Jupiter. Yet at every time and in whatever position these companions ought by rights to appear to us always of the same

546 On the page this small ruled table stands at the head of the leaf, to the left of the paragraph beginning "Therefore the Earth, seen from Venus", with the side-note beside it on the left. Its head runs over two lines, "Diameter apparens Terræ" across the whole table and "conſpecta ex" over the names, and the four columns of figures are headed "Gr.", "Min.", "Sec." and "Tert." (degrees, minutes, seconds and thirds). Blank cells are blank on the page.

size, not to say somewhat larger still at a greater elongation from Jupiter than at a smaller one, because of Jupiter's brightness, which obscures and diminishes them more when they are in its vicinity. For, according to that well-worn optical axiom, the greater light obscures the lesser. Nonetheless, the contrary has been observed more often by Galileo (as can be learned from the *Sidereus Nuncius* [Nuncio Sydereo]) than by us.

[Margin: Cur Jovis Satellites nonnunquam majores appareant.] *Why Jupiter's satellites sometimes appear larger.*

This phenomenon, however, certainly does not arise in any way from a greater distance of the companions from the earth. For those apparent orbits in which they are carried around are very narrow and compressed: the greatest of them hardly runs out to a few minutes in diameter, so that with respect to us they are of no account at all. Nor can the reason be sought in our atmosphere; for otherwise they would always be seen at exactly the same size. Nor in some refraction of the aether: for the aether, as is clearly established from optics, is entirely without any refraction. Therefore, as far as I judge, quite another cause lies hidden beneath, one closer to Jupiter; and none remains but that we establish that there is likewise a vaporous orb around Jupiter. When those companions of Jupiter, or Jovials [Ioviales], enter it, they must, by reason of refraction and of matter a little denser than the rest of the aether, always appear somewhat larger than when they stand outside that atmosphere in the purest aether.

[Margin: Æther refractione omninò caret.] *The aether is entirely without refraction.*

Moreover, sound reason keeps telling us that this Jovial atmosphere can further, both from the zones or bands and from some other spots, by the help of the tele- [Margin: De maculis[[,/;]] Zonis, ſeu f[[a/á]]ſciis certo tempore in corpore Joviali obviis.] *On the spots, zones or bands met with at certain times on the Jovian body.*

scopes not so long ago detected on Jupiter, and partly sketched in the *Selenographia* [Selenog.], p. 42, be fittingly corroborated; indeed, [it tells us] that there is there not only a sphere of exhalations, but that likewise, just as there are clouds around the earth and spots around the Sun, so in Jupiter too there exist certain evaporations and effluvia, according to laws prescribed for them by nature, as well as generations and corruptions. For these zones and spots are not always constant at every time, nor do they keep a similar appearance perpetually: sometimes they are seen scattered over the whole disc, sometimes again in the form of rather oblong zones. Moreover, they agree neither in number nor in form: now a single band appears, equally broad and extended; now two of this kind; now others tapering to a point at both ends, as I remember having observed them several times in the year 1648, on February 19.

[Margin: MaculæJoviales ſunt nubes & evaporationes,diverſæ tamen naturæ à noſtris terrenis] *The Jovian spots are clouds and evaporations, yet of a different nature from our terrestrial ones*

Now these bands and spots visible on Jupiter are, as far as can yet be gathered, clouds, shadows and exhalations, like our clouds and the solar spots; except that they differ in this, that compared with these they are of a different nature, since they seem to be more durable and more constant than our clouds and the solar spots. For these are consumed and dissipated within a short space of time, after a few days have elapsed; but the Jovian ones stay in vigour for some months and more, and are preserved constantly in almost the same appearance before they change or vanish entirely.

[Margin: Cur maculæ Jovis ſemper ut Terreſtres ſint albicantes ?] *Why are the spots of Jupiter always whitish, like terrestrial ones?*

Again, they agree with our clouds in this: they likewise appear whitish and somewhat pale, but by no means blackish, as the solar spots do. That is, because the Jovian spots always turn the same part of their body towards both us and the Sun, no differently from terrestrial clouds when they are viewed from the Sun. From this it is conjectured, not without reason, that the Jovian spots and zones are evaporations and exhalations ejected and breathed out from the Jovian body into the atmosphere.

[Margin: Corpora ætherea volvuntur circa axem.] *The ethereal bodies turn about an axis.*

Unless we would rather establish that these vicissitudes and variations of the spots take their origin from a gyratory motion about an axis. This motion, it is true, even if it is indeed common to all the planets and even to the fixed stars themselves, as will be shown below; nevertheless, since various difficulties attend this opinion, I therefore prefer the former [opinion] for the time being, until more certain things are found out about this phenomenon and about the fixed period of all its vicissitudes.

[Margin: Vniverſos globos cœleſtes orbem habent vaporoſum.] *All the celestial globes have a vaporous orb.*

And so it is by no means absurd, in my opinion, that each of the celestial globes too, like the Sun, the Prince of the ethereal bodies, should continually breathe out and emit exhalations and effluvia of vapours, which make up a vaporous orb. The following reason further recommends this: that four different smaller planets go around Jupiter, as you have learned, and another, recently detected, around Saturn, in a fixed interval of time, just as if they were certain Moons, imitating ours.

[Margin: Comites Jovis & Saturni ſunt inſtar Lunarũ, maximasq́; exerunt vires in commovendis extrudendisq́; exhalationibus.] *The companions of Jupiter and Saturn are like moons, and exert very great forces in stirring up and driving out exhalations.*

For just as each of the two luminaries has no common power to act on these lower things, and to stir and alter especially the sublunary humours and vapours, so, certainly, I have no doubt that these smaller planets too, with all the other [bodies] assisting, especially the Sun and the fixed stars, by virtue of the various aspects which they form with one another, and of the motion of

circumrotation, as well as of a certain natural faculty implanted in these vapours, exert great forces upon Jupiter and Saturn in

[Margin: Anſulæ Saturni quantæ ſint magnitudinis.] *How great the little handles of Saturn are.*

stirring up, expelling and driving out effluvia of various kinds. And this all the more in Saturn, because it is never without its escort of two half-moons, as it were, clinging closely to its body. These are of such bulk that a single half-moon not only comes close to the size of our Moon, but exceeds it almost one hundred and ninety times.

[Margin: Natura otioſa & ſuperflua abominatur.] *Nature abhors what is idle and superfluous.*

For nothing indeed is more certain than that God created nothing whatever in vain, and that nature abhors everything idle. And although I do not altogether deny that those Jovian companions, together with that Saturnian [companion] and the attendants [lateronibus], also exert their powers as far as this earth, yet I think they extend their forces far more strongly to those nearer, adjacent bodies. For by reason of their size and nearness they are very considerable to those bodies; but to us, because of the immense distance by which they are removed from the earth, they come into view in no way unless we are equipped with the best telescopes [Tuboſpicillis].

[Margin: Corpora ætherea univerſa reciprocum patiuntur influxum ſuo modo.] *All the ethereal bodies undergo a reciprocal influx in their own way.*

For just as all the planets and fixed stars act on these lower things, so the Sun and all the other planets, together with all the fixed stars, also undergo a reciprocal influx from the ethereal bodies around them, according to the character of their own power. This power of stirring up and ejecting vapours in those companions, or rather little moons, of Jupiter and Saturn is aroused the more vehemently, the more swiftly they pursue their motion around Jupiter and Saturn.

[Margin: Saturni & Jovis Lunæ,longè velociores ſunt noſtrâ Lunâ.] *The moons of Saturn and Jupiter are far swifter than our Moon.*

For all of them, however many there are, are far swifter in their course than our Moon. The period which the Moon completes in the space of about a month, the First of the Jovials, namely, completes in the space of sixteen days; the Second in seven; the Third in three; but the Fourth and last in one and a half days. Likewise that new Saturnian, as if a rival of that First in the order of the Jovials, also completes its course in almost sixteen days; so that each of the two, the slowest, is carried around Jupiter and Saturn almost twice as fast as our Moon around the Earth. I do not see, therefore, why you should not attribute to these little moons, or wandering stars, their own effects and operations upon the same similar matter too, in like manner as to our Moon.

[Margin: An Mars, Venus & Mercurius nullas foveant aſſeclas ?] *Do Mars, Venus and Mercury keep no attendants?*

But whether several little moons and wanderers of this kind exist around Mars, Venus and Mercury too, I am altogether in doubt. It is clear, indeed, that none at all have been detected so far, that is, with our telescopes worked to a spherical section. But if lenses of hyperbolic section are brought to absolute perfection, as is indeed possible (even by us specimens of no common kind can already be shown to anyone, made by an entirely new, singular and very easy method, which, if it so pleases God, we intend to treat expressly at another time), then certainly, without any doubt, a great many things hitherto unknown will be discovered in the other, inferior planets too, and brought to light. But enough of this.

[Margin: An circa inferiores Planetas orbis vaporoſus deprehendi poſſit ?] *Can a vaporous orb be detected around the inferior planets?*

It follows that I should still add in a few [words] (before we come to the fixed stars) and inquire whether around Venus too, as has indeed been the case with the superior planets, some trace of an atmosphere can be noted. But when I weigh this matter more carefully with myself, I see that it is most probable that a certain vaporous orb surrounds the globe of Venus, no less than it surrounds the Sun and the Moon.

[Margin: Venus Colorem, magnitudinem & figuram quondam mutavit.] *Venus once changed her colour, size and shape.*

For Venus at one time changed her colour, size and shape completely, as St Augustine [D. Auguſtinus] noted in *De Civitate Dei* [de Civit. D E I] from the records of Marcus Varro [Marci Varronis]: *In the heavens a wonderful portent appeared* (so run the wor- ds of Varro) *that the star of Venus (which Plautus calls Vesperugo [Veſperuginem], Homer Hesperus) changed its colour, size, shape and course: a thing that had happened in this way neither before nor since. Adrastus of Cyzicus [Adraſtus CyZicenus] and Dion of Neapolis [Dion Neopolites], noble mathematicians, said that this happened in the reign of King Ogyges.*

[Margin: Quænam illius phænomeni genuina ſit ratio.] *What the genuine explanation of that phenomenon is.*

If we inquire into the physical causes of this unusual event, only three are at hand: either [it lies] in our atmosphere and in terrestrial exhalations; or it really occurred in Venus herself, and she thus suffered some diminution and loss of her body; or it is to be referred solely to some denser matter lying very close to Venus. As for the first explanation, who does not see that it can by no means be proved? The second, too, hardly anyone will grant, and then not easily, unless under the utmost compulsion. What, then, I ask, remains, but that we take refuge once again in the atmosphere of Venus? By means of it all these phenomena, as you understand without my saying so, are explained and demonstrated with almost no trouble.

[Margin: Etiam ipſæ Fixæ evaporationes, & exhalationes exſpirant.] *The fixed stars themselves too breathe out evaporations and exhalations.*

Finally, that alterations and changes also occur around the fixed stars themselves (which all enjoy native light, and no borrowed light at all, as the planets

indeed do), especially by reason of the evaporations and exhalations which they continually breathe out and emit, is inferred from certain arguments that are by no means obscure. And first, indeed, from their twinkling and the agitation of their light.

[Margin: Cur Fixæ ſcintillent ?] *Why do the fixed stars twinkle?*

I am not altogether unaware, it is true, that philosophers have given various causes for this twinkling. Some ascribe it to the size and brightness of the body; others to the motion of the star and to the motion of the light in the star itself; others to distance and to the weakness of our sight; others to the daily motion of the earth, or the primum mobile, and to the intervening medium, or our atmosphere; others again solely to the circumgyration of the stars. Yet if these are weighed exactly, they are not the genuine causes of twinkling, as it is not difficult to show by many [arguments], if we wished to dwell on them longer. All the same, I do not deny that among the causes named some are found that assist, especially the last, namely the circumgyration; but neither these, nor others, even if they contribute somewhat to this matter, suffice on their own.

[Margin: Omnia corpor[[a/á]] ætherea perfecta ſuper axem rotantur.] *All perfect ethereal bodies rotate about an axis.*

It is indeed beyond doubt, just as I too hold it firmly, that all the stars, both the fixed stars and the planets, the Moon excepted, rotate continually about their own axis. Nonetheless, since those very vast ethereal bodies are not, as far as I judge, carried round with so swift and rapid a gyratory motion, the twinkling in no way depends on it.

[Margin: An corpora univerſa æq; velociter circumgyrentur?] *Do all bodies rotate equally fast?*

For, as it seems, the greater the interval by which celestial bodies are removed from us, the slower the motion of circumgyration with which they are endowed. Thus the Earth turns round once every day; the Sun about once every month; but Jupiter, as far as can so far be gathered from its spots, in a much longer space of time; so that the remaining bodies, especially the far more remote ones of the fixed stars, without doubt move about their axis more slowly still.

[Margin: Vera ſcintillationis,ſeu corruſcationis cauſſa.] *The true cause of twinkling, or flashing.*

This, therefore, is not the sole and only reason why the stars flash and twinkle; rather, we judge that another lies hidden alongside it. Namely, the vibrating-out of luminous matter and the continual expiration of vapours and exhalations, which is innate in those bodies (no differently than in the Sun, the Moon and the Earth, though according to their own nature and constitution), is the principal cause of this twinkling. For the more dense and compact this or that body is by nature, or the more rare (since, indeed, in all the ethereal bodies there is not the same mat- ter density), the thicker or the thinner are the exhalations it emits and ejects. And the thicker the effluvia the stars emit, and the greater the quantity, the more vehement and the more conspicuous the twinkling they display.

[Margin: Nova aſtra nonnunquam in æthere exoriuntur rursùsq́ue occidunt.] *New stars sometimes arise in the aether, and set again.*

Finally, great weight is also added to this view of ours by the new stars, which are not only generated in the heavens themselves, among the eternal bodies, but also at times perish again and are dissolved. This has happened with most of them; though of these, some are still seen even now in the highest aether.

[Margin: Stellæ novæ, creſcunt & decreſcunt, colorem lumenq́; diverſimodè mutant.] *New stars wax and wane, and change their colour and light in various ways.*

But all that have ever appeared, however many, were of such a nature that they waxed, waned, and changed in various ways, as much in colour and in the brightness of their light as in size.

[Margin: Stella Polaris aliquando evanuit.] *The Pole Star once vanished.*

Again, others, even among those old fixed stars that have shone continuously on the world for many centuries past, have been entirely extinguished, so that they could no longer be found. For it is reported that after the capture of Byzantium the Pole Star was no longer seen: Gemma Frisius, Book I, Chapter VIII, p. 212, *Cosmocrit.* Then Hyginus, chapter 192, writes that one of the Pleiades, Electra by name, vanished from sight at the time of the destruction of Troy, and that she spreads out her loosened hair in mourning.

[Margin: Nonnullæ Stellæ lucidiores extiterunt.] *Some stars have become brighter.*

Conversely, other stars have become more splendid and brighter, as the author mentioned before reports in the same chapter cited: *Indeed, most* (he says) *[hold that] in the year 1572 and the following the stars in the foot of Orion and in the wing of Corvus were made much brighter and more splendid.* Although these things do not seem altogether absurd to me, yet with most people they will hardly find belief. For this reason I shall adduce other, more recent [cases], and indeed ones beyond all objection, which can certainly never be called into doubt by anyone, unless he is plainly out of his mind, or wishes from an obstinate spirit to fight against the most manifest truth; for almost all the historians of that same time, not to say the astronomers, testify to them unanimously.

[Margin: De novo Sidere in Casſiopeâ anno 1572 exorto.] *On the new star that arose in Cassiopeia in the year 1572.*

First, namely, that in the year 1572, in the month of November, a quite newly risen, or adventitious, star, never seen in the heavens before, appeared in the constellation of Cassiopeia. About it, above all, Tycho Brahe, that incomparable searcher of the stars, and also the most learned Cornelius Gemma, to say nothing of others, have reported a great deal. But so that I may add here only the chief points, which seem to bear on this business of ours, you should know that this very star at first, that is, throughout the whole month of November, surpassed in size all the other stars, both Lyra and Sirius, and even Jupiter itself at its acronychal rising [acronychium]; and that it came as close as

possible to the torch of Venus, when Venus is nearer to the Earth and shines with a fuller face, so that it was seen distinctly even by day, at noon itself.

[Margin: Ejus magnitudo ac claritas, non perpetuò fuit eadem.] *Its size and brightness were not always the same.*

This remarkable size, however, it did not keep throughout its whole duration, but decreased little by little until it ceased to exist altogether. For in the month of December it was almost equal to Jupiter, and somewhat larger than the stars of the first rank, and in February and March it shone somewhat smaller. Thus in April and May it resembled a star of the second magnitude; then it became successively smaller and smaller, so that towards the end of the year it barely resembled a little star of the fifth magnitude, and in the following March it was nowhere to be seen any longer.

[Margin: Quomodo colorem ſucceſſivè mutaverit.] *How it changed its colour successively.*

In the same way, moreover, it did not show a similar light and colour at all times: at the beginning it was seen with a whitish, clear and shining light, with a pleasing and delightful face; afterwards this shining radiance changed its colour into a certain yellowish one, and around the beginning of the spring of the following year into an altogether ruddy one, like Aldebaran; then it took on a slightly livid whiteness, especially around the end of May, and around the end of its apparition an altogether dull and turbid colour, as Tycho noted at length in Book I of the *Progymnasmata*, Part II, Chapter III, p. 301. He adds, on p. 303:

[Margin: Tychonis annotationes de hâc Stellâ anni 1572.] *Tycho's notes on this star of the year 1572.*

This was the appearance and outward condition of the unusual star with respect to the circumstances of its form, size, light and colour, and to their alterations, carefully considered over the whole time of its duration. For although the condition of the air, which in the meantime was sometimes of various kinds and not always uniformly clear, may now and then have presented something in each of these a little differently to the eyes, and this also according to the differing sharpness of sight of those observing, yet this was rather accidental and did not last long. Hence the things we have recorded are not to be judged as coming from some momentary and quickly passing aberration of sight, owing to some hindrance in the medium; but since they were detected in this way by observation repeated long and often while the air was clearer, and compared with one another, no doubt remains that they are correct. Almost the same, but in other words, can be read in the said Cornelius Gemma, Book II, *Cosmocrit.*, Chapter III, p. 123.

[Margin: Nova Stella in pede Serpentarii, qu[[â/á]] ratione etiam aucta & diminuta fuerit.] *The new star in the foot of Serpentarius, and in what way it also increased and diminished.*

Second, not much inferior to this adventitious star of Cassiopeia was the one that many most learned men observed, with great admiration indeed, in the foot of Serpentarius in the year 1604, in the month of October — above

all Kepler, who published a separate little book about it. At first it fell short of the other [star], that of the year 1572, by only a very little in size, and in light and colour as well. *For the reports of almost everyone agree* (says Kepler, p. 6 of the book on the new star) *on the first magnitude: that it appeared larger not only than the stars of the first rank, but also than Saturn, Mars, and Jupiter, which stood near it the whole of October, and which, by the friendly and gentle calm of its light, was easy to distinguish from the turbulence of the star with its flashing.* This star, however, just like that one of Cassiopeia, was afterwards gradually much diminished from that former size: for in the month of January of the following year, 1605, it was hardly equal to Saturn and Arcturus, and in the month of March hardly equal to those stars of the third rank in the knees of Ophiuchus; and so, from day to day up to the month of October, it decreased more and more, until it was entirely extinguished.

[Margin: DeStellâ adſcititiâ in pectore Cygni.] *On the adventitious star in the breast of Cygnus.*

By contrast, another new [star], in the breast of Cygnus, recently born in the year 1600, still presents itself to be seen. At first the star appeared to be of the third rank, somewhat smaller than the one in the breast. As to this size: although I have measured it quite often with instruments, yet I remember that I almost never found it much smaller than [it was when] Kepler first observed it. For he asserts in his little book on the same star, p. 166, that it always kept the same size: it never equalled its neighbour in the breast of Cygnus, namely the old one, but neither was it ever so diminished that it seemed equal to the one in the Beak of Cygnus; and as to colour, it was always seen with a constant and pale [one].

[Margin: Anno 1660 dicta Stella incepit decreſcere.] *In the year 1660 the said star began to decrease.*

With an almost similar appearance too, as we were just saying, we surveyed it at all times up to the year 1660, so that it was always somewhat smaller than the one in the breast, yet equal to the one at the tip of the wing, but with a light a little ruddier and duller. From this, certainly, one may gather that from the year 1600 up to now it has decreased very little indeed. But look: recently, when once again, to observe the stars in Cygnus, I prepared myself — namely on 1660 October 24 — I found, not without great amazement indeed, with the sky very clear, that this new [star], called Antepectus, was much diminished, both in size and in brightness. For when, with fixed eyes, I examined it continuously for some hours together with a certain friend, we found that it was now altogether far smaller: not only than the one in the beak of Cygnus (than which, on Kepler's testimony, it was formerly larger), but also than the one at the tip of the wing; indeed, that it was still a little smaller than the one of the fifth magnitude in the Neck; that it was hardly equal to that one, namely the southern preceding one of the unformed [stars] before the southern wing of Cygnus; and that, no less, it had a far duller light and colour than at an earlier time. But what will happen next — whether it will decrease successively

more and more, or will instead recover its former size again? Time will tell; and for this phenomenon I promise always to be a watchful observer.

[Margin: De admirando novo Sidere in collo Ceti.] *On the wonderful new star in the neck of Cetus.*

But what need is there to recount at such length those things that either existed long ago or have even now entirely vanished, when another phenomenon, wholly new or adventitious, is at hand in the aether itself, one that strikes the eyes of all? Certainly nothing of this kind has ever existed since the founding of the world, at least so far as has been handed down to memory: one that, among the fixed stars themselves, which are coeval [with it], undergoes such various vicissitudes. For that star shines for some time with rays flashing most splendidly on all sides; at a certain time it grows; again it decreases; then it even vanishes altogether and stays hidden for some months; afterwards, in turn, it presents itself again, returned — and indeed always in the same place where it had been seen before — and it holds a place so fixed among the other fixed stars that no parallax at all is detected. It deserves, therefore, that I repeat the history of this wonderful and quite unusual star somewhat more accurately, but still briefly (since we have already treated it expressly and more broadly in a separate little book published in the year 1662).

[Margin: Annotationes Phocylidis de hâc nov[[â/à]] Stellâ in collo Ceti.] *Phocylides's notes on this new star in the neck of Cetus.*

I do not doubt, moreover, that it is not unknown, if not to all, then at least to many of the learned — those who do not always cling to the ground, but at times also raise their minds and eyes on high — what has happened in recent years in the heavens themselves: namely, that Johannes Phocylides, that far from common philosopher and astronomer, in the year 1638, at the beginning of the month of December, on the occasion of a lunar eclipse, noticed a new fixed star, newly risen in the constellation Cetus, and indeed in its neck. He also set down a separate little book about it, where among other things, on p. 197, the following is read about its size: *Finally* (he says) *its size, both to the naked eye and through the telescope, was such as to exceed the stars of the third brightness, such as are those in the mouth and cheek of Cetus, and also the Knot of the Fishes; but it was also perceptibly smaller than the stars of the second magnitude, namely the jaw and the bright one in the Head of Aries.*

[Margin: Stella hæc miras ſubit vicisſitudines.] *This star undergoes wonderful vicissitudes.*

Meanwhile it decreased gradually, and step by step, until at its heliacal setting it was equal to stars of about the fourth rank and magnitude. He adds, moreover, on p. 285: *Note that we have ascribed a disappearance to this new phenomenon observed by us. See p. 197. And indeed that is how the matter stands. In midsummer we rose several times very early in the morning, after it would otherwise have risen heliacally; we surveyed the sky most diligently with intent eyes; we saw the Knot, the Mouth, the Cheek, the Jaw of Cetus, and the other neighbouring stars round about; no trace*

of the new star could then be observed. Nor I was the only observer; several suitable witnesses [were] with me;

[Margin: Fullenii Obſervationes.] *Fullenius's observations.*

indeed, the most distinguished man Bernardus Fullenius, professor of mathematics, also searched for the phenomenon many times. All in vain. A sure sign that it had, as it were, disappeared. But on 1639 November 7, in the Julian year then running, after continuous clouds with us for some days, indeed weeks, when the sky was at last clear in the evening, I happened to go out and observed it — and anyone is still free to observe it — in precisely the same place, in the same position as before.

[Margin: Nova Stella in colloCeti creſcit & decreſcit, nonnunquam etiam penitùs evaneſcit.] *The new star in the neck of Cetus grows and decreases, and sometimes even vanishes entirely.*

From this, therefore, you understand well that this new star vanished in the year 1638 and appeared again in the following year, in the month of November, and indeed in exactly the same place among the fixed stars themselves where it had shone before. Fullenius, professor of mathematics at the Academy of Franeker, also found this to be so many times: namely, that this star strictly kept to its vicissitudes, sometimes being present in the sky, sometimes entirely hidden. About it the same author wrote the following to a friend in the year 1644, in the month of September: *Some years ago* (he says) *I observed in the sky a phenomenon like a star, mostly of the third magnitude, which, however, according to the seasons of the year not only changed its size but also at times stayed hidden for days, indeed months — as also this year, when up to this day it has not yet appeared; and this also happened two years back, when it could not be seen before September 23.*

[Margin: D.Jungii Obſervatio.] *D. Jungius's observation.*

This star of Cetus was likewise seen by D. Joachimus Jungius [Joachim Jungius], professor and rector of the Hamburg Gymnasium, in the year 1647, on February 18 and 20, up to its heliacal setting; *but from then on* (as he wrote to D. Eichstadius) *although carefully sought by me from the month of July, it has not yet appeared.*

[Margin: Autoris Obſervationes.] *The author's observations.*

Again, in the year 1648, on January 5, I remember that I too observed it: larger, indeed, than the Knot of the Line and the one in the mouth of Cetus, yet smaller at that time than the Jaw, as I noted in my notebooks [Adverſariis]. From that time, however, I confess that I observed it only rarely; for, distracted by other business and studies, I almost forgot it, thinking that it had by now perished altogether. So too in the year 1659, in the month of August, while it was being carefully searched for by me and Dn. M. Kretzschmer, not a trace of it was detected. But on December 14 of the same year, at 9^h in the evening, I saw it very well together with my mechanician [automaturgo], who at that time was assisting me with observations, and I also observed it accurately with our great brass sextant: it was found to be larger than the one at the cheek of Cetus, of the fourth magnitude, yet smaller than the one in the mouth of Cetus, of the third magnitude; its colour was somewhat gloomier. From that very day it

decreased gradually up to its heliacal setting. When I had noticed this, and had also called to mind what is recorded above, I resolved firmly that I must watch it more diligently in future, so that I might find out properly whether everything would happen in that way again in the following year, 1660. Accordingly, as soon as Cetus had risen heliacally in that year, on every clear night, whenever observations were being carried out, I searched anxiously for that star, together with certain others who were then at my side; but nowhere, believe me, did it appear, as if it had never existed in the nature of things. Indeed, not even the least sign of it was detected with the optical tube, namely from the beginning of the month of July up to the beginning of September; except that on the first and second of the same month, as it were a very tiny star, like [one] of the sixth or seventh magnitude, it seemed to be present in the very place where it used to appear. From the second day, however, up to September 10, the sky was entirely cloudy, so that nothing was observed by us. But on September 10, when, as is my custom, I was again contemplating it, look: it was seen quite clearly, like a little star of the fourth magnitude, hardly smaller than the one at the cheek of Cetus; with this [star] and the Jaw it always forms a straight line, so that on that same night I measured it very well from various stars. Its colour [was] somewhat ruddy and dull; in light and brightness it appeared much inferior to the Jaw.

[Margin: Colorem non ſemper eundem præ ſe fert.] *It does not always show the same colour.*

After this it grew perceptibly from day to day: for on September 18 and 20 it had already reached the size of the one in the mouth of Cetus; on the 27th, 29th and 30th it was larger than the one in the mouth of Cetus; on October 10 and 13 it seemed equal to the Jaw, but surpassed it in brightness, and in its light it appeared a little whiter; on October 18, 20 and 24 it was certainly larger than the Jaw, indeed than the Bright Star of Aries, yet a little smaller than the one in the more southern Tail of Cetus. Moreover, just as it had a whiter colour, so too it was endowed with a much livelier and more vibrant light. And these are the things that have so far been observed by us. What will happen next, however — whether it will acquire a still greater size, or will instead soon begin to decrease again — time will tell.

[Margin: Nova in collo Ceti in altiſſimo æthere verſatur.] *The new [star] in the neck of Cetus is situated in the highest aether.*

Since all these things have truly been so, who, I ask, will now judge, or can judge, otherwise than that in the highest aether itself, among the fixed stars themselves, new adventitious bodies have arisen outright; that they have sometimes grown, again decreased, and varied in colour and light, being now brighter, now darker and duller; indeed, that in their own time they have entirely vanished?

[Margin: Cur Autor paullò prolixius novam Stellam in Collo [[C/c]]eti deſcribere voluerit.] *Why the author wished to describe the new star in the Neck of Cetus at somewhat greater length.*

I wished to give the short history of this wonderful star somewhat more fully in this place, with this above all in view: that very many singular and hitherto unheard-of things have been noticed in this new star, and unusual things are still detected in it every year — such as have certainly been observed in no other star since the founding of the world. For whatever [stars] of all the others have shone forth up to now vanished again after a certain space of time had elapsed, and never returned to view in turn.

[Margin: Miras ſubit vicisſitudines.] *It undergoes wonderful vicissitudes.*

But this star in the Neck of Cetus vanishes every year and appears again after some months — and indeed at first as the least little star of all, of dim light and of a reddish and gloomy colour; then it grows gradually, both in bulk and in light, and varies its colour: as may be learned more fully from our *Mercurius*, especially from the history of this wonderful star published in the year 1662.

[Margin: In eodem ſemper Cœli loco affulget.] *It always shines in the same place in the sky.*

Everyone now rightly marvels at the phenomena of this star, and all the more because the genuine causes of its marvellous appearances have so far been so little explored. Above all, what makes the matter more intricate is that this star, whenever it shines forth at all, always stays fixed in the same place in the sky, and does not change its distance from the other fixed stars by even a few seconds, not to say minutes.

[Margin: Autoris de iſto novo Sidere ſententia.] *The author's opinion on this new star.*

Nevertheless, however extremely abstruse the matter may be, let us still disclose our view on it. First, however, you should know, kind reader, that the said star is situated in the highest aether among the very bodies of the fixed stars, since no parallax at all can be detected in it.

But whether that most vast body (which, according to our hypothesis, is 287,496,000 [times] larger than the Earth, as is clear from our *Mercurius*, p. 94; while it sometimes equals the Bright Star of Aries in magnitude) could, after a few months — indeed weeks — have elapsed, be entirely dissipated again, or be reduced to nothing, and that from some natural cause, and shortly afterwards be generated and coagulated anew and grow into so immense a bulk, I think hardly any of the philosophers will readily concede.

[Margin: An Stella illa ſpatio aliquot menſium posſit in nihilum planè redigi, ac rursùs coagulari.] *Whether that star can be reduced entirely to nothing in the space of some months, and coagulated again.*

Nor would I readily grant that that star is moved away from us upward in a straight line, or can be carried up so far that it appears so slight, indeed is entirely extinguished, and then, in its own time, seeks lower regions again along the same straight line, so that it is seen in turn with a large face. This is precisely because such a rectilinear motion is utterly foreign to all reason, and nothing similar is detected in any other body.

[Margin: An motui aliquo rectilineo obnoxia ſit.] *Whether it is subject to some rectilinear motion.*

Then, how very vast an interval, I ask, counted from the fixed stars themselves, would be required to accomplish this straight motion upward before this new star seemed to pass from the magnitude of the second [order] to that of the sixth or seventh order? This would be easy to demonstrate by calculation, if we wished to dwell on these matters longer. Not to mention in what space of time, and by what most rapid and extremely violent motion, this phenomenon would have to be reproduced. Finally, it also seems altogether most absurd that this immense bulk should, in a wonderful way, by God's infinite power and absolute will, be utterly destroyed every year — and indeed sometimes twice, as happened in the years 1661 and 1663 — and shortly afterwards be created again and produced immediately; and that in such a way that those newly and successively created bodies always emerge so strictly in the same place in the sky that they do not deviate toward this or that quarter even by a few seconds, let alone by minutes.

[Margin: Sidus hocce in ColloCeti neutiquam à DEO recens eſſe creatum.] *This star in the Neck of Cetus was by no means newly created by God.*

Since this is so, what explanations then remain, you will ask, by which all those said phenomena met with in that new star in the neck of Cetus can suitably be saved? None indeed, of all that have presented themselves so far (yet let others be free to judge), except one single explanation, soon to be disclosed, by means of which all the phenomena are rightly and successfully saved and explained.

[Margin: Quænam de hâc mirâStellâ rationi convenientior ſit ſententia.] *Which opinion about this wonderful star is more in accord with reason.*

First, however, you should know that this recent star of Cetus dwells in the highest aether among the fixed stars themselves, as we have already sufficiently demonstrated in the short history of this wonderful star, p. 158. If, just as to the Sun, the Moon and the other planets, we attribute to this body an atmosphere of its own, or vaporous orb, the matter is on safe ground and, as it were, already settled without much circumlocution.

[Margin: Datâ, circa illam Stellam atmoſphærâ omnia phænomena optimè ſalvantur.] *Given an atmosphere around that star, all the phenomena are saved very well.*

For then it is by no means necessary that this body, as often as it shines on us, should each time be generated anew from an innate property and some essential power, and again after some months be corrupted or dissipated. Second, there is no need either for it to be subject to some straight motion by which it would be carried away and in turn let down again, most swiftly, beyond what can be said, in a short space of time. Third, nor shall we be forced to take refuge in the omnipotence of the Divine Power. For the atmosphere that surrounds that star properly discloses and demonstrates each of the phenomena — provided, that is, that it is granted; indeed, under pressing necessity, one must by all means

grant a vaporous orb there too, since by no other hypothesis, in our judgement at least, are all the phenomena saved more readily and more correctly.

According to our opinion and hypothesis, therefore, as was shown above, all the bodies of the world belch out and eject evaporations and effluvia, though at some times in greater abundance, now thicker, now thinner, which in their own time are in turn dissipated and vanish.

[Margin: Vniverſa corpora Mundana exſpirationes emittunt.] *All the bodies of the world emit expirations.*

And so around this new star too there is an atmosphere, made up of the exhalations and evaporations issuing from that very body. These expirations, however, flow out more copiously at different times, according to the constitution of their body and the cooperation and influence of the [bodies] round about — just as happens in the Sun and in our Earth. For here among us clouds and vapours are more frequent in autumn than in summer, and the sky is generally more cloudy in winter than in spring; so it is also with the Sun, which brings forth more spots, faculae and shadows in one year than in another.

From this hypothesis, therefore, it follows altogether that when generally all those thicker expirations that cling for some time in the same atmosphere have been dissipated, and the atmosphere has been purged of those denser clouds and dregs, and the aether has been rendered more purified, then, I say, this new star shows its genuine face, as regards magnitude, light and colour.

[Margin: Qua ratione nova illa Stella toties occidat atq́; rursùs oriatur.] *In what way that new star so often sets and rises again.*

But when vapours and evaporations again rise gradually from the body in the open hemisphere of the star facing us, they in turn impede the view of that star to some extent, so that it is seen with more difficulty than before; and hence it appears to all of us successively paler, gloomier and somewhat darker, and all the more so the more frequent the exhalations that emanate from that body and the denser they become. So this star must necessarily decrease gradually as far as appearance goes, and finally, when those clouds, mists and aethereal effluvia have been packed together on every side, vanish altogether, as if it had never existed in the sky — until in turn that matter of the vapours is gradually thinned and made finer, namely when all those exhalations have been dissipated; then it seems to come to life again, to arise, to grow, and to put on its former genuine face. Our terrestrial exhalations too quite often induce such phenomena in the stars, so that now this star, now that, appears now smaller, now gloomier and darker, or redder.

[Margin: Quomodo creſcat ac decreſcat.] *How it grows and decreases.*

Therefore, since these aethereal vapours and evaporations, like terrestrial ones, do not continually burst forth and rise from that celestial body uniformly, of altogether the same density and quality and at the same time, and do not always come together and pack together in the same manner, it can certainly happen that the said star does not always appear to us of the same magnitude, nor of the same colour, nor of the same light (as observation has so far clearly

shown; but is noticed in one year somewhat larger and brighter, in another, again, somewhat smaller, redder and darker, even when it otherwise shines at its greatest. For that reason it is seen by all the inhabitants of the Earth now of the second, now only of the third magnitude.

[Margin: Quo pacto diverſam induat magnitudinem & colorem.] *How it puts on a different magnitude and colour.*

Moreover, the more tenacious and durable these expirations are, the later the said new star meets the eye, and the longer it stays hidden; so that it keeps no fixed or periodic time at all for its first appearance, but begins to blaze up first now in this month, now in that, according to the constitution and quality of the matter.

[Margin: In eodem ſemper Cœli loco; ſed non ſtato tempore redit.] *It always returns in the same place in the sky, but not at a fixed time.*

By this reasoning we now also easily understand how the often-mentioned star always stations itself in the same place in the sky and by no means deviates to the sides: since the star never really perishes entirely and is born anew, but only apparently sets, by reason of overshadowing, veiling or obscuring.

In a quite similar way it is not absurd that some of the remaining fixed stars too can be clouded over and obscured, so that they sometimes shine smaller and darker than usual; indeed, that they can be entirely covered, so that they do not appear anywhere at all, according to the condition of a denser atmosphere — as is recorded to have happened once in Venus and in stars in Orion. Perhaps, believe me, there were even more of these to which the same metamorphosis happened.

[Margin: Fixas poſſe nonnunquam quà magnitudinem variari, ac penitùs etiam evaneſcere.] *That the fixed stars can sometimes vary as regards magnitude, and even vanish entirely.*

But who ever directed his eyes so carefully to those phenomena in the past? Did not almost the whole world, persuaded, that is, by the Peripatetics, hold this very thing among the most absurd [notions]? The ancients would surely sooner have sought water in the sea than have expected such wonderful alterations and changes in the aether itself.

[Margin: Corpora ætherea vicisſitudinibus eſſe obnoxia, Veteres inter abſurda retulerunt.] *That aethereal bodies are subject to vicissitudes, the ancients counted among absurdities.*

But I am thoroughly convinced that it has happened many times, in the past as now, that some fixed stars, as far as appearance goes, have grown somewhat for the reasons given above, and others in turn have decreased. For at this very time some are found much smaller, and some also larger, than Hipparchus and others of the ancients determined them, as will be said more fully a little later — also in our *Machina coelestis*.

[Margin: NonnullæFixæ haud parùm hucuſq; mutatæ ſunt.] *Some fixed stars have changed not a little up to now.*

Yet it is utterly wrong to impute this difference of magnitudes to the carelessness and inattention of the observers; rather, I hold that it must be ascribed solely to their vaporous orb, which surrounds those bodies. And so, given this hypothesis, there is no need at once either to take refuge in divine omnipotence or in occult qualities, or to invent new generations and corruptions of such very vast bodies, and to grant a true accretion and decrease, a real augmentation and diminution. For even some of those [stars] which have grown and decreased, changed their colours and entirely perished (although I would not deny either that other fixed stars too, in our view, can really be generated by their own nature, in their own way, and dissipated again in their own time, like the bodies of comets) may have been created at the very beginning of the world, even though they first came into view after many centuries had elapsed, and a little afterwards perished in turn. Nor is it an objection that hardly any of the new stars has ever risen again once it has set.

[Margin: Nonnullæ tantummodò apparenter pereunt.] *Some perish only apparently.*

The reason is this: that there, in their atmospheres, such immense mists and extremely dark cloudings can sometimes arise, and become so condensed and packed together, that they are dispersed scarcely, if at all, after some centuries; and others are never broken up at all, because of the more tenacious matter of the vapours and the more solid structure of the evaporations. Hence those stars are wrapped in perpetual darkness, so that at no time any longer, even though they are really present, can they be seen and observed by us.

[Margin: De Stellâ novâ in pectoreCygni quamdiu inCœlo ſubſtiterit.] *On the new star in the breast of Cygnus: how long it remained in the sky.*

Into their number that new [star] in the breast of Cygnus must rightly be counted, which from the year 1601 up to the year 1659 and 1660, for a span of almost sixty years, shone clearly like a star of the third magnitude; but from that time it began to decrease, and a little later it perished entirely, so that for three or four years now it has entirely ceased to be among the other fixed stars: just as is now evident to all who look into the sky. Whether it will appear again, or will remain so entirely obscured and covered for ever, surely deserves to be observed accurately by us and by posterity, so that at last, some day, the causes of these appearances may be explored more correctly and more clearly, and uncovered.

Therefore, finally, we again and again rightly conclude that wonderful changes and alterations, and also generations and corruptions, occur not only around the Sun, the Moon and the other planets, as around the Earth, but also around the fixed stars themselves; and moreover that each body has its own atmosphere, into which, from its own essential property, it ceaselessly emits and breathes out the most diverse vapours and exhalations, now thicker and denser, now finer and thinner, to purge and cleanse its body — though far more of them at one time than at another, according to the different influences of the other aethereal bodies.

[Margin: Corpora univerſa Mundana habent ſuas atmoſphæras,in quibus variæ mutationes, alterationes atq; generationes accidunt.] *All the bodies of the world have their own atmospheres, in which various changes, alterations and generations occur.*

In this way, indeed, and with this difference: that the thicker vapours do not depart very far from the body, but always remain in the atmosphere — which rotates perpetually about an axis together with its body and turns in perpetual motion like a vortex — and scarcely ever go beyond it, like the solar spots and our clouds; so that they persist there for some time, according to the nature and constitution of the matter, and are condensed; then, in their own time, they are resolved and dissipated again, so that they can return once more to their body, from which they arose.

[Margin: Craſſiores halitus in atmoſphærâ perſiſtunt, atq; cum eâ ſimul circũgyrantur.] *The thicker vapours persist in the atmosphere and revolve together with it.*

For with every aethereal body it has been so arranged by nature that it has a faculty both expulsive and attractive, and a singular force and inclination to preserve itself.

[Margin: Omne corpus æthereum ſingularem potentiam habet ſe conſervandi.] *Every aethereal body has a singular power of preserving itself.*

Whatever exhalations and expirations, therefore, are expelled from any body, whether by an internal or by an external motion, that very body in its own time draws those very effluvia back again and takes them in, so as to preserve itself, as we have said, and to subsist in its state at all times. Just as usually happens with the exhalations and vapours that our land and sea breathe out. For at times they flow out abundantly into the surrounding air; but then, when occasion offers — namely through rain, mist, dew, blight, snow, hail, hoar-frost, etc. — they return to the earth again, whether they are pressed down by the force of the Sun, or drawn by the earth through some implanted natural faculty. But this has been said of the denser and thicker expirations.

With the finer and thinner effluvia of aethereal bodies, however, the account is indeed almost the same, except that not rarely they depart and withdraw much farther from their body (just as the finer and drier vapours of the earth ascend to a higher place): not only as far as the outer limit of the atmosphere of the body from which they are expelled, but even beyond it; so that they can spread themselves through the whole aether, according to its motion, implanted in them from the beginning (of which we shall say more in Chapter VIII).

[Margin: Subtiliores æthereorum corporum exſpirationes etiam ultra atmoſphæram aſcendunt.] *The finer expirations of aethereal bodies ascend even beyond the atmosphere.*

Indeed, when the course they have taken so permits, it can happen that these mobile vapours, because of the great affinity of all aethereal bodies that exists among them all, not only enter the vortex, or vaporous sphere, now of this, now of some other body or planet, and also of the Earth itself, but sometimes even

pass entirely through it: namely when they have taken on a certain definite impetus, and a certain path toward this or that region of the sky. So while those aethereal vapours and exhalations wander in this way through the whole aethereal air, it not rarely happens that at one time they are thinned out, and at another that these richer and more tenacious vapours thicken and coagulate more and more; so much so that sometimes, out of many rarer exhalations, little clouds and celestial clouds scattered here and there, now one or another, now several more solid and denser aethereal clouds, or corpuscles and nuclei of different sizes, can be generated by this condensation and coagulation.

[Margin: Quâ ratione ex evaporationibus & effluviis æthereis tenuioribus, corpus quoddam denſum,ſive Cometa generari poſſit.] *How a dense body, or comet, can be generated from finer aethereal evaporations and effluvia.*

When these are then joined together and packed close, as other little clouds, or bodies and nuclei, come upon them from the surrounding atmospheres, and also with rarer matter running in between, they finally grow, according to the matter available, into an astonishing mass in that part of the aether. Now when an immense heap of this kind, of nuclei piled one upon another with rarer matter scattered among them here and there, gradually reaches such maturity and solidity that it is able to receive the rays of the sun and reflect them in every direction, and is brought so near to the earth that it falls under our sight, then, I say, it is called a comet; and this is the very thing that constitutes a hairy star.

This cometary body, then, is compounded of the most diverse matter, of the effluvia of diverse aethereal bodies, rarer as well as denser, and of innumerable more solid corpuscles and nuclei, and it grows for a certain time until it attains perfect maturity, according to the constitution and nature of that matter. In the same way, in turn, once it has passed what is, so to speak, its manly age, it begins to grow old: that is, this matter and these nuclei begin, one after another, to be dissolved, separated and thinned, until they are entirely dissipated and reduced to the thinnest and subtlest aethereal vapours, so that at last, at some time, they may return to those globes and to the origin from which they were breathed out and from which they drew their beginnings. This is just what usually happens with the solar spots, with our clouds, and with terrestrial exhalations.

[Margin: Cometarum corpora ex diverſis Cœleſtium corporum effluviis conſtant, atq; certo tempore creſcunt, rursùs decreſcunt.] *The bodies of comets consist of the effluvia of various celestial bodies, and grow for a certain time, [and] decrease again.*

[Margin: Quâ ratione Cometa diſſolvatur.] *How a comet is dissolved.*

Of these, the latter are reduced by the force of the winds and the heat of the Sun into the thinnest air, and sometimes into rain, snow, dew, etc., as we touched on above, and so are carried back again to the earth from which they arose; the former, on the other hand, are in their turn dissipated and dissolved above all by that more vehement circling motion of the Sun. In sum, to embrace our view in a few words: I say that all celestial bodies have some power that

promotes alteration, generation and corruption; next, that the vaporous matter belched out of the bodies is most strongly inclined, by a nature implanted in them, toward coagulation and condensation (these aethereal vapours grow together of their own accord when they are left to themselves, just as clouds do of themselves); and then also that the coagulated matter and the gathered nuclei separate only with difficulty, unless they are both dissipated and resolved by some force, whether external or internal, which so far has not yet become known to us, so that at last that matter may be able to return to where it was ejected.

[Margin: Sententiæ Autoris ſumma, de generatione & corruptione Cometarum.] *Summary of the author's view on the generation and corruption of comets.*

[Margin: Materia illa Cœleſtis, ut Terreſtris ex inſitâ facultate naturali propenſionem habet ad condenſationem.] *That celestial matter, like terrestrial [matter], has from an implanted natural faculty an inclination toward condensation.*

Hence it comes about, since all the wandering and fixed stars, being extremely vast bodies, unceasingly breathe out and eject exhalations and vapours, that successively much finer and thinner matter is dissipated here and there through the whole aethereal air; this matter afterwards, by the power of gathering itself together that nature has implanted in these effluvia (as we find in our terrestrial vapours), gradually fly together and are condensed. For the whole of nature seeks condensation; and that rarer matter of the celestial bodies, too, has a physical inclination and a natural propensity to take condensation upon itself, as toward its own perfection — certainly no differently from all sublunary things. Indeed, the denser the celestial matter (that is, the evaporations) is, the more perfect it is. From this it follows — since matter always gapes more and more after a new form — that the aethereal vapours and exhalations gradually gather together more and more, and, coming together, are condensed by that implanted, hidden natural faculty.

Moreover, in whatever globe's atmosphere such matter, placed there, and a rich vapour are first coagulated, it is in the vaporous orb of that planet, and in that place, that the comet takes its beginning, or is, so to speak, first born.

[Margin: Prima Cometæ nativitas.] *The first birth of a comet.*

For example, let it be that its true birth took place around Saturn, and that the matter began to coagulate there. When this matter has become a little denser and has been made more suitable (for the denser a body is, the fitter it is for motion), it begins to move (for what reasons, and in what manner, will be told more fully in Book IX), and indeed toward the extremity of that system or vortex; at last it even leaves this entirely and enters the vastest aether. Indeed, from time to time, according to the course of the path of the newly coagulated matter, or comet, it enters the nearest system of a neighbouring planet, especially if other exhalations happen to be present there with which this matter, which arose earlier, can be united and joined — while it nevertheless goes on toward where, from its first beginning, the more powerful matter,

that is, began its impetus, and toward which it tends (for the lesser yields to the greater); and indeed with a nearly straight motion, as will be properly demonstrated in Book IX.

[Margin: Quomodo moveatur.] *How it is moved.*

So while that cometary matter thus pursues the path it has begun and set before itself, all those vapours and exhalations that it meets here and there in that tract associate and join themselves, of their own accord and easily, to that greater body in motion. As a result it not only grows continuously, but also acquires a greater impetus for moving itself (for motion produces motive force) toward the region which the greater part of the exhalations set out at the beginning to make for.

[Margin: Quâ ratione tractu temporis in curſu incrementa Cometa capiat.] *How a comet takes on growth in the course of time during its journey.*

Since, then, more and more of the finer matter, which is dispersed everywhere through the aether from various atmospheres, clings to that moving body from every side, it finally grows into a certain vast body. And just as this body is composed of the most diverse matter of diverse planets, so it is also composed of various corpuscles and nuclei, partly denser, partly rarer, and likewise of different kind and shape — now round, as being most closely akin to union, now of another [shape].

But to state still more clearly how the effluvia of all the planets, too, can sometimes coalesce into one cometary body: know that when, for example, matter newly coagulated and condensed in the vortex of Saturn acquires a motion toward the Sun, it must then necessarily enter first the orb of Jupiter, then those of Mars, the Earth, Venus and Mercury, and so at last also that of the Sun itself. On this journey, since certain effluvia are sometimes given off from any system of the planets, it happens, as we touched on above, that by a certain magnetic nature of joining themselves together they easily coalesce and cling also to other matter that comes upon them, and also that this more dilute matter that it meets accompanies of its own accord that [matter], already in motion, denser and larger.

[Margin: Quo pacto omnium Planetarum effluvia in unum corpus Cometicum coeant.] *How the effluvia of all the planets come together into one cometary body.*

Because in homogeneous bodies there is always a certain quality by which their parts are borne toward one another, attract one another mutually, and tend toward the same place, as Aristarchus of Samos rightly and skilfully says in his *System of the World*.

[Margin: Corporibus homogeneis, ineſt qualitas quâ partes illorum ad ſe invicem feruntur, atq; in eundem tendunt locum.] *In homogeneous bodies there is a quality by which their parts are borne toward one another and tend toward the same place.*

Above all, this newly formed comet acquires no small strength and force when it passes through the sphere of the Sun. Since far more frequent evaporations are found there than elsewhere (namely the finer matter of the spots, frequently belched out of so vast a body), the comet therefore at that time also grows, most of all and perceptibly, into a great heap and mass, and at that time too it becomes much more compact.

[Margin: Verſans Cometa circa Solem, maxima plerumq́; incrementa haurit.] *A comet moving about the Sun usually takes in its greatest increase.*

For, as far as can be gathered from the nature of the solar spots, the solar exhalations and smoky evaporations are strongly inclined toward condensation, more than the effluvia of all the other planets; so that you may, not undeservedly, regard that solar matter in comets not only as the more principal [matter], but also as that natural glue, so to speak, and binding, which more and more unites, glues together and binds all the rest of the gathered matter.

[Margin: Evaporationes Solares adcondenſationem valdè propendent,atq́; exhalationes reliquorum Planetarum quaſi conglutinant.] *Solar evaporations are strongly inclined toward condensation and, as it were, glue together the exhalations of the other planets.*

Hence almost all comets, namely when they are nearest to the Sun and the Earth, are nearly at their largest and densest of all.

[Margin: Cometæ quando Soli Terræquè ſunt vicinisſimi,plerũq́; ſunt maximi & denſisſimi.] *Comets, when they are nearest to the Sun and the Earth, are usually at their largest and densest.*

At the same time, however, it cannot be denied that comets decrease again a little afterwards, that is, before they have entirely traversed the orb of the Sun. The reason is this: just as all aethereal bodies breathe out exhalations at a certain time, so they also reclaim and attract them in their own time. From this it happens that, as long as the comet moves within the sphere of the Sun, the solar evaporations do indeed cling to it; but before it leaves that sphere, the Sun calls back and attracts those vapours again. Hence [the comet] must necessarily decrease, since at the least the principal and greater part of the solar expirations leaves the comet within that sphere, and suffers itself only reluctantly to be torn away, as it were, from its native soil, or to be led away and drawn out of it. I would have the same said also of the evaporations of the other planets.

[Margin: Quare Cometæ plerunq́; decreſcant, priusquam Orbem Solarem trajiciunt.] *Why comets usually decrease before they pass through the solar orb.*

But indeed, you will say, does not this very point most strongly contradict your opinion: namely, that the vapours of any planet like to linger in their own orb or sphere, in which they were emitted, and leave it only with great difficulty?

[Margin: Cujusq́; Planetæ halit[9] ſphæram, ſeu orbem ſuum ægrè deſerunt.] *The vapours of each planet leave their own sphere, or orb, only reluctantly.*

Not at all, certainly. Even if I grant that the exhalations of Saturn can of their own accord enter the sphere of Jupiter, Mars, the Earth, Venus and all the

rest; likewise the evaporations of Jupiter the spheres of Mars, the Earth, Venus, etc.; and again the expirations of Mars those of the Earth, Venus, Mercury and the Sun, and so on in succession, I do not on that account contradict myself. For it is certain that all the planets, and the Earth itself, recognise the Sun as their centre. Therefore the sphere of Saturn, as that of the body most remote of all from the Sun, embraces all the other spheres within itself; next, the sphere of Jupiter contains those of Mars, the Earth, Venus, Mercury and the Sun; again, the orb of Mars [contains] the orb of the Earth, Venus, Mercury and the Sun; the sphere of the Earth [contains] the sphere of Venus, Mercury and the Sun; the sphere of Venus comprehends those of Mercury and the Sun; and finally the orb of Mercury surrounds only that of the Sun, so that the sphere of the Sun is the innermost and smallest of all.

[Margin: Planetæ quotquot ſunt, Solem pro centro habent.] *All the planets, however many there are, have the Sun as their centre.*

Therefore, although the exhalations of Saturn enter the spheres of the other planets, they nevertheless do not, if you consider the matter carefully, leave their own sphere, since the sphere of Saturn, as the largest, comprehends all the others. The same is to be understood of the evaporations of Jupiter: the smaller spheres, indeed, of the in- ferior planets, such as Mars, the Earth, Venus and the Sun, they can enter; but their own (namely Jupiter's) they can by no means exceed, so as to reach the sphere of Saturn. In the same way, the effluvia of Mars may indeed pass through the orbs of the Earth, Venus, Mercury and the Sun, but not pass beyond that of Jupiter. The same holds for those finer and drier exhalations of the Earth, if they ever pass beyond the atmosphere; but they rarely get that far, because for the most part they are so very impure and heavy that they can scarcely leave the vaporous orb.

[Margin: Quousq́; Planetarum materia, ſive halitus propelli poſſit.] *How far the matter, or vapour, of the planets can be driven.*

The vapours of Venus, on the other hand, can pass through the sphere of Mercury and the Sun, but cannot reach the Earth; and I would have you understand the same, in succession, of the effluvia of the remaining lower [planets]. Therefore, since the sphere of the Sun is the innermost and smallest, in this respect the solar vapours and exhalations are not allowed to range out into any other orb.

With these things supposed, our view stands firm: namely, just as the solar expirations associate themselves with the comet, and join themselves to it, only in its orb, so also, within the same sphere of the Sun, before the comet has passed entirely through it, the principal part of the exhalations remains in that sphere, so that they may return to their vortex and their origin, namely the Sun, from which they came out.

[Margin: In orbe Solis præcipua materia Cometica datur.] *In the orb of the Sun the principal cometary matter is supplied.*

Accordingly, as soon as comets enter the sphere of the Sun, they must certainly grow, by reason of the solar matter that clings there in abundance;

but before they leave that sphere of the Sun again, they also begin to decrease, because the Sun calls back and attracts what is its own, and also lets anything go out of its sphere only reluctantly. Similarly, in the course of time the comet is diminished more and more. For shortly afterwards Mercury too, then Venus and the Earth, if any [exhalations of theirs] are present, and finally Mars and Jupiter: each, that is, calls away and draws to itself its own exhalations, so that in the end nothing but that first matter of Saturn is left on its own (that is, when comets have consisted of the effluvia of all the planets). And this matter is no less consumed and dissolved at last, or rather so thinned that a return to its own body is likewise granted to it.

[Margin: Qu[[ò/o]]modo Cometa attenuetur, & quâ ratione, & ordine ſinguli Planetæ ſuas exſpirationes vicisſim repetant atq; attrahant.] *How a comet is thinned, and in what manner and order the individual planets in turn reclaim and attract their own expirations.*

In this way, then, comets are generated from the diverse effluvia of diverse planets and grow, and in turn decrease and are dissolved, so that in due time a way back may lie open, successively, for these exhalations and smoky evaporations to their own body at last, and to the origin from which they came forth. For, as has repeatedly been urged already, the matter of any planet flows back together, by a certain implanted, natural, magnetic power, to that very body, as to its own principle, from which that matter was drawn out.

For this reason I am entirely convinced, since almost all the comets that come into our view usually take their path through the sphere of the Sun, and so approach the Sun at a certain time, namely when they are nearly closer to our Earth (for comets are almost always seen only in quadrature and in opposition to the Sun), that then too, at nearly every time, the first dissolution of comets takes place near the Sun, as about the true centre of the planetary system, and that, by reason of the matter called away by the Sun, as we touched on above, they begin to decrease there.

[Margin: Omnes propemodùm Cometæ per ſphæram feruntur Solis.] *Almost all comets are carried through the sphere of the Sun.*

[Margin: PrimaCometarum diſſolutio, plerunq́ue fit circa Solem.] *The first dissolution of comets usually takes place about the Sun.*

For, as the history of comets bears witness, no comet has ever shone which, once it had passed the Sun as the centre of the universe (that is, according to the inclination of its trajectory line), did not at once and continuously begin to decrease as to matter and substance, [and to be] rare- fied and attenuated: as is easily detected from the rarity of its body and the weakness of its light.

There is no reason, however, for you to think that each and every comet is always generated or composed from the effluvia of all the planets; only some are. For some are born first in the sphere of Jupiter, and these cannot reach Saturn; others are generated originally in the domicile of Mars, and to these there is passage neither to Saturn nor to Jupiter; others in turn remain in the

sphere of Venus, namely those that took their beginnings there; and so on, so that one [comet] may consist of nothing but the evaporations of the Sun.

[Margin: Non univerſi Cometæ ex omnium Planetarum evaporationibus conſtant.] *Not all comets consist of the evaporations of all the planets.*

Among these, some can be carried across in such a way (especially if they are thrust out of the atmospheres of the superior planets) that they in no way touch the orbs of the inferior planets, but must leave them to one side; and so they are made by no means sharers in those [planets'] effluvia. For they are altogether unable to attract the exhalations of the spheres they do not enter. Therefore one comet consists of the evaporations of only some [planets], two, three or more, namely by reason of the trajectory they take, and of their course, according to the quarter toward which they direct it: all of which we shall treat more fully in its place. And these are the things we proposed to say on this occasion about genuine comets, which are born from the subtler and purer effluvia of the ethereal bodies.

It remains for us still to touch briefly on those pseudo-comets, or spurious ones, which are produced from the more impure and grosser evaporations in the individual atmospheres of the individual bodies. On these my view is this: that sometimes, indeed, a certain body is coagulated and composed from such grosser exhalations, as if from their dregs; but it is never permitted to leave the atmosphere, so that it is generated and corrupted in the vaporous orb, and also lasts only a short space of time.

[Margin: De pſeudo-Cometis: ubinam, & quomodo generentur.] *On pseudo-comets: where, and how, they are generated.*

This body, however, is wrongly called a comet; it is only a chasma [chaſma], or a meteor [meteoron], such as we not rarely see here among us in the surrounding air.

[Margin: Dari chaſmata, & meteora ætherea.] *That there are chasmata and ethereal meteors.*

In the atmosphere of the Sun such[547] special comets (if these momentary bodies may be so called) are observed at almost every time: namely, those solar spots. Just as they are produced in the atmosphere from more impure and denser exhalations, so also they always persist in it until their destruction, and, as the observations of everyone teach, never desert it and leave it; so that these bodies, if we wish to speak properly, are nothing but pseudo-comets, or rather solar meteors.

[Margin: De meteoris Solaribus.] *On solar meteors.*

Moreover, it seems very consistent [with reason] that such bodies or momentary meteors are generated in the atmospheres of all the other planets too, likewise in their own way, and are not rarely present there. But that they do not strike our senses in that way, and so distinctly, as the terrestrial and solar ones do, anyone may readily gather: namely, because of the excessive

[547]the page prints talcs; the sense is tales, "such"

distance, the rarity of the matter (for no one, surely, will deny that the effluvia of the other planets, even those very much grosser, are far thinner than these of ours and the solar ones) and the smallness of the body, they can in no way be discerned. For I think that the whole apparent atmosphere of Saturn and of Jupiter is scarcely 2′ or 3′ in diameter, and [those] of the remaining planets are also scarcely somewhat larger: whether anything can be seen in them there, either with the naked or with the armed eye, judge for yourself, I beg you, wise reader.

[Margin: Quanta ſit Saturni, Joviſq; apparens atmoſphæra.] *How large the apparent atmosphere of Saturn and of Jupiter is.*

But let it suffice to have merely touched on these spurious comets; let us return to the genuine ones, so that we may now also discuss where they acquire that varied and most diverse colour which they display. For it is plain that not all comets, at every time, have shown a similar and identical colour: some, namely, were splendid and bright, like the Sun; others fiery, ruddy and glowing red; others yellow and golden, like amber, which are otherwise called Chrysii [Chryſios]; others silvery and white; others leaden, pale and somewhat livid; others blackish and dusky; others changed colour in succession.

[Margin: De variis Cometarum coloribus, eorumq́; origine.] *On the various colours of comets, and their origin.*

These most diverse colours certainly arise from nowhere else than from this: that [comets] are generated and coalesce from the most diverse matter of diverse bodies; then, that they are not always equally compacted and consolidated; and further, that they consist now of more and smaller nuclei, now of fewer, larger and more solid ones. For just as no one can deny that each planet enjoys a different light and an unlike colour (since Saturn appears somewhat livid and ashen; Jupiter whitish and bright; Mars glowing red and fiery; Venus silvery and shining white; Mercury yellowish; the Sun golden and fiery; the Moon white and mild, at all times without exception, as is manifest to anyone once their hair [capillitio] and their adventitious light are taken away), so likewise the effluvia that are breathed out and cast forth from the individual bodies of the planets must also be of the most diverse colour.

[Margin: Singuli Planetarum peculiarem colorem præ ſe ferunt, quem eorum effluvia etiam æmulantur.] *Each of the planets displays its own particular colour, which their effluvia also imitate.*

By reason, therefore, of the most diverse exhalations and evaporations, and insofar as comets have been coagulated from these or those expirations of this or that planet, or consist of one or another predominant and prevailing matter, to that extent they reproduce this or that colour; and this colour likewise appears the more intense or the more subdued, the rarer, or the denser and more solid, the matter, together with the nuclei, from which it is generated and composed.

Hence [it may be inferred] that comets as splendid and bright as those that appeared in the year 119 before the birth of Christ, which Seneca mentions in chapter 15 of Book VII of the *Natural Questions*, and likewise in the years

after the birth of Christ 1264 and 1521, were born entirely of the Sun, or of solar matter, or at least that in these same hairy stars the solar effluvia were the more powerful. Next, in those that were of a ruddy, glowing red and fiery colour, the matter of Mars and of the Sun prevailed; such as those in the year of Christ 662, 1526, 1554, 1556 and 1618. Those, however, that were seen yellow and golden, like the one in the year 1531 and 1533: these, I say, arose alike from Jupiter and Mercury and alike from the evaporations of the Sun. Again, of those that showed a silvery and whitish colour, such as appeared in the year 1463, the greater part of the matter was breathed out from Venus, perhaps, Jupiter and its companions. But as for those so pale, somewhat livid and dark: certainly, if they did not coalesce from the mere effluvia of Saturn and Jupiter and their companions, those effluvia at least predominated in them; such as were seen in the years 1240, 1558, 1569, 1580, 1585, 1590, 1596, 1607, and also 1652.

[Margin: Ex coloribus Cometar. haud malè divinari poteſt, ex cujus Planetæ exhalationibus corpus Cometicum ſit compoſitum; vel ſaltem cujus materia in eo prædominetur.] *From the colours of comets one can guess, not badly, from which planet's exhalations the cometary body is composed, or at least whose matter predominates in it.*

With this mournful and gloomier face the greatest part of comets usually shines; and I think this comes about because most, or very many, take their birth only from the atmospheres of Saturn and Jupiter and their evaporations, and abound in those same effluvia.

[Margin: Cur pleriq́ue Cometæ pallidi & ſublividi ſint ?] *Why most comets are pale and somewhat livid.*

For these planets, being most vast and immense bodies, are able, together with the companions attached to them, always to breathe out much matter and to supply it to comets. Not to mention that the vapours of these planets rarely come together into a very dense mass; and are only with difficulty condensed so far that large and solid nuclei are produced; so that lividness and pallor must necessarily arise from this, and such comets must take on a leaden, or ashen, colour.

I add that from this foundation, and from these colours of comets, distinguished by their variety, one can also in some measure judge, not badly, both about the native soil of any comet (from where, and from which planets' atmospheres, they were born and cast out) and also conjecture whether they will depart from the Earth and the Sun a little or a great deal, and how far (though only in a rougher way), and which will be higher and more remote.

[Margin: Ex coloribus quadantenus conjicitur, quo inCœli loco quivis Cometarum prognatus,& quousq́; à terrâ propemodùm diſceſſurus ſit.] *From the colours one conjectures to some extent in what place of the heavens any of the comets was born, and roughly how far it will depart from the Earth.*

I hold, moreover, that pale and somewhat livid comets can advance higher and farther than the ruddier and more splendid ones. The reason is this: the matter of the latter, just as it flows out from Mars, Mercury and the Sun, is so

dispersed again in their spheres and orbs and flows away; whereas [the matter] of the former, according as they took their origin from the spheres of the superior bodies, [is dispersed there] if they in turn travel to where they came from.

Accordingly, as far as I can scent it, it will also be open to us to divine to some extent about their parallaxes: namely, that the paler and ashen comets always have smaller parallaxes, and the ruddier ones larger; since [the paler ones] travel higher, or farther, namely to their own spheres. And although you may think that I am here weaving a rope out of sand, yet when the observations of comets are considered and accurately weighed, these things are not so far removed from reason.

[Margin: Cometæ pallidiores pleruńq; altiores, rubicundioribus exiſtunt.] *Paler comets are usually higher than ruddier ones.*

For the comet of the year 1577, which was conspicuous for a somewhat livid whiteness, had receded toward its end to 1733 semidiameters of the Earth, as Tycho testifies in the proem on that same comet. The comet of the year 1580, which was likewise somewhat pale, reached as far as Saturn. The comet of the year 1585, which was endowed with a dim, rare and nebulous light, had no parallax at all toward its departure, as one may read in Tycho's *Epist.* to the Landgrave; so that it is certain it reached as far as Saturn. In the comet of the year 1590, which likewise shone with a pale and somewhat dark face, Tycho detected not even a trace of parallax (*Epist.* to the Landgrave, p. 174). Finally, since the comet of the year 1618 was far ruddier than our [comet] of the year 1652, it was for that reason also found to be far lower. For the former reached only as far as the Sun, whereas the latter, the pale one, was much higher than the Sun: indeed its parallax toward its departure could barely, if at all, be perceived.

[Margin: Exemplis probatur opinionem hanc non adeò eſſe inconvenientem.] *It is shown by examples that this opinion is not so unfitting.*

But whether this phenomenon holds in all comets, or only in some, observations will teach. I urge and counsel posterity, and above all the sons of the astrologers, to attend to them seriously, so that at last they may some day lay more solid foundations for their judicial astrology, and may in future have clearer grounds for divining the outcomes of times and affairs from the distinct and most diverse colours of comets.

[Margin: Conſilium pro Aſtrologis: quâ ratione ex coloribus aliquid ſolidius conjecturare poſſint.] *Advice for astrologers: by what means they may conjecture something more solid from the colours.*

Now something must also be said about those comets that rather often take on one colour after another in their trajectory, and above all, what the genuine reason for this phenomenon is. You will easily perceive this, however, if you weigh well everything we mentioned a little earlier: namely, that this can happen in those comets that arose from unlike expirations of diverse bodies.

For one that was born only from the evaporations of a single planet always shows, as far as I understand, a similar colour; except that brighter

[Margin: Vnde nonnulli Cometæ in trajectione colorem mutent, & quinam ſint conſtantioris coloris.] *From what cause some comets change colour in their trajectory, and which are of a more constant colour.*

and more splendid it may sometimes appear, according to the different degrees of density and rarity; but the rest, which enjoy differing matter, are very much subject to change. For as often as new matter comes in abundantly from one body after another, so often do the colours change. Above all, the exhalations of Mars and of the Sun seem to contribute much to this business: for as soon as these accrue to some new body of comets, they vary it greatly in respect of colour.

Accordingly, comets in the sphere of the Sun and near it are mostly seen glowing red, according to the matter supplied; and again, as soon as they recede from the Sun once more, they become[548] paler: because Mercury soon, and then Mars, take back their own, and at last only the evaporations of Jupiter and Saturn are left, which, according to the nature of their body, appear nothing but somewhat livid and growing pale.

[Margin: Quare in regione Solis Cometæ ſæpiùs rutili videantur.] *Why comets in the region of the Sun are rather often seen glowing red.*

Therefore, to the extent that comets successively take on increases and decreases, and become partakers of the matter of this or that body, to that extent, I say, the colours change, and for it, according, that is, to the different degrees of density and rarity, they become more vivid. So that all this may shine out the more clearly, we shall set it out in a diagram below.

Now, before we pass on to other matters, let us sketch comets, and new stars as well, according to our own view, though only with a rougher brush, so that you may have some general knowledge of all the things that remain to be set forth by us in their place and accurately unravelled. A comet, therefore, is an ethereal, hairy or bearded, temporary body; as to its head, not altogether globular but disc-shaped; formed from the vapours and smoky evaporations both of the Sun and of all the remaining planets; and indeed composed of manifold corpuscles and nuclei, partly round, partly various irregular ones, with rarer matter sprinkled here and there. Its entire matter, like the bodies from which they came forth, enjoys no native light at all, but draws all that it has entirely from the Sun.

[Margin: Quid reverà, ſit Cometa, ex menteAutoris.] *What a comet really is, in the author's view.*

Its tail, moreover, is produced from solar rays reflected and refracted, while they are arrested in a certain rarer medium, as in a cometary atmosphere surrounding the comet, on the side turned away from the Sun. For the rest, the body itself is movable: not indeed with a double motion, in some eccentric

[548] the page prints redduntut; the sense is redduntur, "they become"

and about an axis, as the other ethereal and eternal bodies are, but only with an almost rectilinear motion, always turning its face almost directly toward the Sun, according to that impetus which that earlier atmosphere impressed upon, and communicated to, the first coagulated matter once it was ejected.

With new stars, however, the case is somewhat different. For although they agree in many respects, in many they also differ not a little: as much in respect of the place where they first coalesce as in respect of the matter from which they are generated, and also in respect of the shape they display; to say nothing of other things.

[Margin: Quid ſint novæ Stellæ, & quomodo procreentur.] *What new stars are, and how they are produced.*

To begin with, new stars, no differently from comets, are ethereal temporary bodies; which, however, draw their origin by no means from the effluvia and evaporations of the wandering bodies, but from those of the fixed [stars] themselves. And just as the bodies of the fixed [stars], according to the common opinion, are entirely immobile and endowed with native light, so those new ones, which are produced from them, come together, coalesce and grow from luminous matter in some fixed place, upon one centre, into some one body and an almost round nucleus; and, immobile in that same place, (com- mon motion of all the fixed [stars], if you except that) they subsist continuously, just like the bodies from which they arose. Moreover, they appear far brighter and more splendid (since they consist of one single, large, very dense nucleus) than the offspring of the planets, which is produced from various very small and mostly rarer nuclei and from thinner matter.

[Margin: Quare novæ Stellæ Cometas claritate ſuperent.] *Why new stars surpass comets in brightness.*

Above all, they surpass comets greatly in brightness, because they are illuminated not by the Sun but by the innumerable fixed [stars] themselves, and then because they revolve unceasingly about an axis, as is natural to all the coeval fixed [stars]; and from this the twinkling and that vehement vibration of light arise in part. For the rest, these new stars lack any tail entirely, and scatter no hair at all round about them; nor indeed can this ever happen, because they do not consist of many differing nuclei and bodies, as comets do, but of one single nucleus only, namely an almost round body, which in no way grants passage to the rays either of the Sun or of other stars, so that a tail could be displayed from the refraction and reflection of the rays — however much new stars too may have their own atmospheres.

[Margin: Cur nullam exhibeant Comam.] *Why they display no hair.*

Add to this that the Sun's rays cannot reach that far; indeed, even if it be granted that they can get there, they nevertheless do not exert such great force there as to imbue with light a body that is dark in itself. For the whole diameter of the Sun, seen from some fixed [star], appears, because of the immense distance, scarcely 6‴ in size; so that from it a perceptible tail could by no means

be produced, even if the matter were not so compact on every side but rarer and sprinkled through it.

[Margin: Quanta ſit diameter Solis ex Fixis ſpectata.] *How large the diameter of the Sun is, seen from the fixed [stars].*

Indeed, even though the Sun should cast its rays all the way to the fixed [stars] unimpaired and equally vivid and strong, and some new body fit to receive them should also be supposed, nevertheless a tail arising from them would certainly by no means come into our sight.

For since there is almost no sensible ratio between the sphere of the fixed stars and the great orb [orbis magnus], so that almost all parallax in the fixed [stars] vanishes entirely (if you except a very few seconds), the whole great orb is therefore like a centre of that immense sphere of the fixed [stars], which stands to the former as 1 to 41,250; and so it will make no difference whether the bodies of the fixed [stars] are considered from the Sun or from the Earth.

[Margin: Ratio orbis magni ad Sphæram Stellarum Fixarum.] *The ratio of the great orb to the sphere of the fixed stars.*

Therefore all tails, even if they were granted to new stars by the Sun, entirely elude the keenness of the eyes, as though covered by the bodies. For tails are always cast toward the part opposite the Sun. But whatever is opposite to the Sun is also opposite to us, because, as you have learned, the whole great orb is of no moment at all with respect to the sphere of the fixed [stars]. Therefore whatever lies hidden on the rear side of the stars by no means meets the eyes; and so the tails of new stars too, if any are produced by the solar rays, are by no means seen. Rather, at every time, in whatever place of the ecliptic the Earth or the Sun may stand, new stars shine entirely stripped of hair, as has also been observed in all that have ever shone forth.

[Margin: Non tamen omnes novæ Stellæ pari ratione generantur & producuntur; ſed aliæ tantùm apparenter oriuntur,& occidunt.] *Not all new stars, however, are generated and produced in the same way; but some only apparently rise and set.*

Yet I do not think that each and every new star is first born and takes its beginnings from matter supplied and flowing in, still less that it really grows little by little, decreases again in the same way, or finally vanishes through the rarefaction and attenuation of the matter; but that new stars can also sometimes arise in another way and set entirely — that is, according to appearance; [stars] which nevertheless in reality, in the same place of the heaven, perpetually unharmed remain, as we have already lightly touched on above, at p. 378, and shall, God granting, also discuss more fully in its place. Let this, then, suffice on these matters for the present. Let us return to comets, in order to remove those doubts that might perhaps be raised against our hypothesis, and then to answer the questions duly and accurately.

First, then: since we have asserted that the planets, and all ethereal bodies as well, continuously breathe out effluvia and eject exhalations, which, according to an innate natural faculty, are condensed, increased, resolved, diminished and

dissipated, and also, in time, are recalled and attracted by those bodies from which they came forth, it is asked, not without reason, what that is which brings all these things about and perpetually preserves each body in its own state.

[Margin: Quænam ſit cauſa agens, in expellendis effluviis & exſpirationibus ex corporibus æthereis, & generandis Cometis.] *What the agent cause is in expelling effluvia and expirations from the ethereal bodies, and in generating comets.*

As for the first cause, if it need only be pointed out, the matter will be dispatched by us very briefly: namely, that the supreme Founder and Preserver of the universe created those ethereal bodies in such a way, and preserves and rules them in such an order, that it can by no means happen otherwise than that they constantly emit breaths and vapours and take them back again. But truly, this would be to have recourse to the first cause acting freely, which is entirely unbecoming to one discoursing on natural and physical matters. Therefore let us leave that first cause aside for the present and pass on to the second cause.

If this is to be inquired into accurately and duly, it will, beyond all doubt, seem to you, my reader, an arduous business, and the discussion likely to be lengthy. But however laborious the matter really is, let us nevertheless deal with it briefly, and so sketch the thing itself, explain it, and compare it with other things known in themselves, that what is sought may easily be grasped by most people — although we deliberately do not designate it by one single name, as was indeed done partly by the ancient and partly by the younger philosophers.

[Margin: Non adeò ardua res eſt, cauſam hujus rei indagare operantem, ſive expellentem.] *It is not so arduous a matter to track down the operating, or expelling, cause of this thing.*

Of these, some from among the ancients, such as the Platonists, and from among the more recent Jordanus Bruno [Giordano Bruno], Egydius Personerius de Robberval [Gilles Personne de Roberval] etc., said that it is the soul of the world and of the ethereal bodies, governing all things in this way; others would have it that it is a spirit; others, an intrinsic form; others, an occult quality; others, a magnetic virtue; others, an essential property; others, a vegetative faculty — to say nothing of the remaining opinions.

[Margin: Variæ Philoſophorum hâc de re opiniones.] *Various opinions of the philosophers on this matter.*

But to us it makes no difference whether you name it thus or otherwise hereafter; let everyone be free to do so. Nor let us go down into the arena with anyone on that matter, nor on this occasion seize upon any particular one of all those opinions as the truer. We lay down only this: that it is that very natural faculty, implanted in the celestial bodies and in the whole ethereal air, which expels, ejects, condenses, rarefies, dissipates, dissolves and attracts all things, and accomplishes everything, which brings about all those things in and around our Earth and performs that very function — the faculty, namely, which begets metals and produces trees, plants and fruits of every kind from the earth, and

thrusts out and ejects the most diverse vapours and exhalations, from which various meteors are generated and then preserved for some while in the air; and at last, in the course of time, those breaths are brought back, or attracted, to the earth in certain ways.

[Margin: Cauſam iſtam eſſe planè eandem, quæ in, & circa Terram talia operatur; quo nomine autem diſtinguenda ſit, perinde eſt, dummodo rem ipſam intelligas[[./,]]] *That this cause is entirely the same as the one that brings about such things in and around the Earth; but by what name it should be distinguished makes no difference, provided you understand the thing itself.*

That very faculty, I say, is the one which brings forth all our sublunary meteors, and at the same time exhales, condenses, attenuates and in turn dissipates all the matter of the solar spots, and preserves all things in a perpetual series; this very [faculty] too all co- mets and new stars it begets from the ethereal bodies, preserves for some while in the aether, and afterwards dissolves; and at length, in its own time, it recalls the matter to whatever body it flowed out of, restoring and returning to each its own.

[Margin: Quo fine corpora Mundana effluvia & exhalationes emittant, & ejiciant.] *To what end the bodies of the world emit and eject effluvia and exhalations.*

Just as this intrinsic virtue (if one cares to designate that very thing by this name) always tends, on our earth and in its air, toward this end, and exerts its forces so that it may purge and thoroughly cleanse the Earth and the air — namely by breathing out superfluous exhalations and evaporations, and by condensing, attenuating and again resolving them — so it operates in almost the same way, but nevertheless in its own manner, so that that superfluous matter, now rarer, now somewhat thicker, is breathed out and thrust out from all the celestial bodies (no differently from what is admitted by all in the case of the Sun, around the spots), and at times is condensed and aggregated. From this [matter], finally, it sometimes brings forth and completes new stars and comets, that is, temporary stars and temporary planets; and afterwards it again resolves, attenuates and dissipates those newly arisen bodies, according to the proportion of the matter of which they consist, since they can by no means at all attain such absolute perfection as those bodies obtained from God, Best and Greatest, at the beginning of the world; and hence they too are not so very perennial and durable, but only perishable and temporary.

[Margin: Corpora ætherea temporaria nunquam ad perfectionem coævorum corporum perveniunt.] *Temporary ethereal bodies never attain the perfection of the coeval bodies.*

And nature produces all these things, and in turn destroys them, to this end: that the stars and the aether, like the Earth and the air, may be purged and cleared of dregs. For individual natural things always gape after perfection and a better form, which consists above all in purity.

But if you would rather ascribe this power, which works and accomplishes all things, to that struggle which takes place in the celestial bodies no differently than on the Earth, and which expels and thrusts out now some, now other

abundant parts (since they likewise consist entirely of heterogeneous parts), it will do me no harm.

[Margin: Quilibet globus æthereus,habet varias innatas qualitates.] *Every ethereal globe has various innate qualities.*

For I have no doubt at all that every ethereal globe also has its own heat, its own cold, dryness and moisture, heaviness and lightness — yet according to the character of its own virtue; and accordingly it does not seem absurd that the drawing-out of effluvia from the stars can come about by reason of those qualities implanted in all bodies. But if anyone should not yet be willing to rest content, I will say these few things into his ear, with which, I hope, he will be very well content, and would make no retort [?]. Tell me, pray: of how many causes and effects of sublunary things, much nearer to us, are we entirely ignorant? Why then do you wonder that we cannot understand and uncover so very accurately and fully that genuine cause which accomplishes all those things in those far more remote bodies?

[Margin: Multarum rerum etiam ſublunarium cauſæ, & effectus ignorantur.] *The causes and effects of many things, even sublunary ones, are unknown.*

It is enough, I think, to know just this: that in the ethereal bodies there is that very expulsive and attractive virtue which is natural to our Earth. But if anyone puffed up with learning should persuade himself that he sufficiently understands that intrinsic cause which works all things and inheres in the Earth and in sublunary things, he, indeed, has already rightly seen through the whole business, and will at the same time easily comprehend in what way each and every thing in the ethereal bodies is drawn out, preserved and brought back, so that nothing at all remains to be added.

[Margin: An corpora ætherea tantùm materiæ, ſine detrimento ejicere valeant,quò tot immenſa corpora aſcititia generari queant.] *Whether the ethereal bodies can eject so much matter without detriment, so that so many immense adventitious bodies can be generated.*

Second: another question now arises — namely, whether it can ever happen, even granting that all the celestial bodies continuously eject and breathe out vapours and exhalations, that they are able to supply so much matter for generating and constituting such immense bodies, namely new stars and comets? Further: supposing that this can happen, will so much depart from those bodies as a result that they necessarily decrease little by little from day to day and appear successively smaller? Especially since new stars and comets are bodies of immense size, as is abundantly clear from Book VI above, pp. 529 and 530, where it was demonstrated that the comet of the year 1652 was four times larger than the Moon in respect of the area of its disc — to say nothing of the new stars, as being round bodies, and to set before our eyes only that single one which shone in Cassiopeia in the year 1572 and, as Tycho attests concerning that same star at p. 485 and p. 549, exceeded the bulk of the Earth three hundred times — according, mind you, to the Tychonic hypothesis; but

according to ours and that of the Copernicans, it was indeed far larger even then?

[Margin: Quantæ fuerit magnitudinis nova Stella in Caſſiopeâ anno 1572.] *How large the new star in Cassiopeia in the year 1572 was.*

We answer that the celestial bodies can by all means exhale and breathe out matter so very copious, or such abundant exhalations and vapours, that such very vast adventitious bodies can be generated; and that nothing whatever departs from those bodies as a result, nor do they incur any detriment or decrease. For this generation is only a circle of nature, as Aristotle says (*De Mundo*, chapter 5): while some parts are ejected, others are preserved for a time, and others are taken back; and so there is there, as it were, a perpetual succession of things, just as here on the Earth and in our sublunary things, where unceasingly some things arise, while others set and perish.

[Margin: Vt circa Terram, ſic circa corpora ætherea indeſinenter alia oriuntur, alia occidunt.] *As around the Earth, so around the ethereal bodies, some things unceasingly arise and others set.*

And that very thing which Aristotle, in the same chapter cited, attributes to sublunary things belongs by the best right, I think, to ethereal things: *"Since meanwhile,"* he says, *"births check rampant deaths, and the deaths of things in turn relieve overflowing births. But the single safety, compounded out of them all, itself remains for ever: since, as things stand opposed to one another and in turn give way and prevail, the universe is preserved for all time, contracting no harm."*

[Margin: Etiamſi in partibus detur generatio & corruptio, totum tamen in æternum conſervatur.] *Even if there is generation and corruption in the parts, the whole is nevertheless preserved for ever.*

For who does not know that from the Earth, day by day, an enormous quantity of vapours and exhalations is expelled and ejected, and has flowed out continuously since the beginning of the world — from which clouds, rain, hail, snow, lightning, thunder and all the other meteors (among which the Peripatetics also count the comets themselves) have arisen — and that nonetheless the Earth has not decreased on that account, nor has anything been lost from the waters, nor, as Aristotle rightly says, has it contracted any harm, still less is any detriment from this detected up to now?

[Margin: Terra licet immenſos vapores & exhalationes continuò emiſerit, nullam tamen contraxit noxam.] *Although the Earth has continually emitted immense vapours and exhalations, it has nevertheless contracted no harm.*

Much less do those very vast ethereal bodies, which exceed our Earth in bulk so many times over, suffer either any detriment or any decrease from this — as much in respect of quality as of substance, or of apparent diameter. Again, the more evaporations and exhalations so many immense bodies, exceeding our Earth so many times over, can breathe out and emit, the more easily and quickly some adventitious body can be coagulated from them.

[Margin: Corpora ætherea univerſa, plus materiæ, quàm Terrâ ejiciunt & exſpirant.] *All the ethereal bodies eject and breathe out more matter than the Earth.*

For the individual planets, too, not infrequently contribute their own [share] to a comet; and the Earth as well brings to it its own most subtle breaths, far thinner than the twilight matter, as we did not deny above. But above all, the companions of Jupiter and the attendants of Saturn, together with the newly detected companion, promote the generation of comets not a little. Since these are very large bodies, they also continually thrust out very many exhalations. How large the individual planets really are — and indeed according to the opinion of various authors — the following table clearly shows. It contains not only the volumes of the bodies, from the distances and diameters, but also the ratios of the diameters and volumes of the planets to the Earth.

[Margin: Quantæ magnitudinis ſint brachiaSaturni, nec non Comes ejus, atq; Circum-Joviales.] *How large the arms of Saturn are, and also its companion, and the Circumjovials.*

549

Table showing the size of the planets and their ratio to the Earth
[TABULA Magnitudinem Planetarum & rationem eorum ad Terram exhibens.]

[549] the table fills the page in one ruled frame below its title. The planet names (Sol, Luna, Saturnus, Jupiter, Mars, Venus, Mercurius) are set sideways in the first column, each centred on its block of seven rows; here each is given in its block's first row, and a rule divides the blocks. The column headings are set in two tiers, the quantity above and its unit below, the unit row given here in italics as printed; the first column carries no heading, and the last no unit. The apparent diameters are printed in two columns under one heading, minutes and seconds, given here as one value. In the last column each ratio is two figures joined by a printed rule, the Earth's diameter first; a 1 standing first means the planet is the larger, a 1 standing second that the Earth is. The authors' names are printed in Latin: Ptolemæus, Copernicus, Tycho Brahe, Keplerus, Bullialdus, Ricciolus, Hevelius, and in the planet blocks "Albategn. & hyp.Ptol." (Saturn) and "Albategnius & Ptol." (Jupiter to Mercury).

550

Now it will also serve our purpose to add how great the attendants [laterones] and the companion of Saturn are, and likewise the Circumjovials, both with respect to us and with respect to Saturn and Jupiter, as regards visible diameter and solidity. You will find all of these, carefully computed by us, in the following small tables, and indeed according both to Kepler's hypothesis and to ours. In our hypothesis the Sun, and so also Saturn and Jupiter, are removed farther from the Earth by quite a notable interval, yet somewhat less than

[550] the table fills the page in one ruled frame below its title, which repeats that of the previous page; it continues the previous page's table for the same planets and authors in the same order. The planet names (Sol, Luna, Saturnus, Iupiter, Mars, Venus, Mercurius) are set sideways in the first column, each centred on its block of seven rows; here each is given in its block's first row, and a rule divides the blocks. The column headings are set in two tiers, the quantity above and its unit below, the unit row given here in italics as printed; the first column carries no heading, and the last no unit. In the last column each ratio is two figures joined by a printed rule, the Earth's solidity first. The authors' names are printed in Latin as on the previous page, but the first name of each planet block from Saturn on reads "Ptolem. & Albategn.", Ptolemy first.

according to Riccioli. For our parallax is set at about 40″, but Riccioli's at only 28″. Hence our mean distance of the Sun from the Earth comes to 5160 semidiameters of the Earth [S. T.], Riccioli's being 7300 S. T., whereas Kepler's mean is only 3410 S. T.

[Margin: Quanto intervallo Sol à Terrâ diſtet.] *How great an interval separates the Sun from the Earth.*

II. Table showing the distances of the companions from Saturn and Jupiter, together with their diameters as seen from Saturn and Jupiter [II. Tabula exhibens Diſtantias Comitum à Saturno & Jove, unà cum diametris illorum ex Saturno & Jove apparentibus.]

[551]the table stands below the prose, in one ruled frame. The first column carries the row labels and no heading; the last carries the units, printed in italics and given here as printed, and no heading. Columns two and three stand under the heading "According to Kepler's hypothesis" [Juxta Hypotheſin Kepleri.], columns four and five under "According to our hypothesis" [Juxta Hypotheſin Noſtram.]; each heading is given here in the second row, over the first of its two columns. The Earth is written in the labels and units with its sign, ♁. The apparent diameters are printed as two figures, minutes and seconds, given here as one value. In the last two rows each ratio is two figures joined by a printed rule, the Earth's figure first.

	Distance from its planet, apparent on the Earth	Distance from its centre in semidiameters of the Earth	Distance from its centre in miles	True diameter in miles	Diameter apparent from its centre	Distance from its centre, apparent on the Earth	Distance from its centre in semidiameters of the Earth	Distance from its centre in miles	True diameter in miles	Diameter apparent from its centre

III. Table showing the size of Saturn and of the attendants, or its arms [III. Tabula exhibens magnitudinem Saturni & Lateronum, ſeu brachiorum ejus.]

	According to Kepler's hypothesis	According to our hypothesis	
Least distance of Saturn from the Earth	27100	41000	*Semid.* ♄
Longest diameter of Saturn, apparent	1′ 12″	1′ 12″	*Min. & Secund.*
True	8135	12310	*Milliar.*
Interval between the arms of Saturn, apparent	0′ 52″	0′ 52″	*Min. & Secund.*
True	5875	8890	*Milliar.*
Breadth of one arm, apparent	0′ 10″	0′ 10″	*Min. & Secund.*
Breadth of one arm, true	1130	1710	*Milliar.*
Shortest diameter of Saturn, apparent	0′ 34″	0′ 34″	*Min. & Secund.*
True	3842	5812	*Milliar.*

[552] the table stands below the first, in one ruled frame. The first column carries the row labels and no heading. The first five columns of figures stand under the heading "According to the Keplerian hypothesis" [Juxta hypotheſin Keplerianam.], the last five under "According to our hypothesis" [Juxta hypotheſin Noſtram.]; each heading is given here in the second row, over the first of its columns. The units are printed below the headings in four columns only, and are given in the third row in italics as printed. The angles are printed as two figures, minutes and seconds, given here as one value. The four Jovian companions are numbered I–IV, I on the line of "Circum-Jovial", II–IV alone below it.

	According to Kepler's hypothesis	According to our hypothesis	
Circumference of the middle circle	12070	18260	*Milliar.*
Area of the middle circle	11590000	26530000	*Mill. Quadr.*
Solidity of the whole of Saturn with the arms	62865000000	217700000000	*Mill. Cubic.*
Solidity of Saturn without the arms	45400000000	157200000000	*Mill. Cubic.*
Solidity of one arm	8732000000	30250000000	*Mill. Cubic.*
Ratio of the diameter of the Earth to the longest diameter of Saturn	11 — 4 3/4	1 — 7 1/6	
Ratio of the diameter of the Earth to the shortest diameter of Saturn	1 — 2 1/4	1 — 3 3/8	
Ratio of the solidity of the Earth to the solidity of Saturn	1 — 24	1 — 59	
Ratio of the solidity of the Earth to the solidity of an arm	1 — 3 1/3	1 — 11	

553

IV. Table of the apparent diameters of the Sun, as if seen from the Earth and the other primary planets, at their mean distances from the Sun [IV. TABULA APPARENTIUM DIAMETRORUM SOLIS, Ex Terrâ & Reliquis Planetis primariis quaſi ſpectati, ad diſtantias ipſorum à Sole Medias.]

Authors	From Saturn	From Jupiter	From Mars	From the Earth	From Venus	From Mercury
	Min. Sec.	*Min. Sec.*	*Min. Sec.*	*Min. Sec.*	*Grad. Min. Sec.*	*Grad. Min. Sec.*
Ptolemy and al-Battānī	2′ 24″	3′ 38″	8′ 14″	32′ 18″	1° 8′ 40″	0° 35′ 50″
Copernicus	3′ 34″	6′ 16″	21′ 4″	32′ 44″	0° 45′ 30″	1° 31′ 38″
Tycho Brahe	3′ 22″	5′ 56″	20′ 26″	31′ 0″	0° 43′ 6″	1° 26′ 52″
Kepler	3′ 14″	5′ 52″	20′ 14″	30′ 32″	0° 42′ 10″	1° 18′ 40″
Boulliau	3′ 26″	6′ 18″	21′ 34″	32′ 52″	0° 45′ 24″	1° 25′ 12″
Riccioli	3′ 12″	6′ 24″	21′ 16″	31′ 56″	0° 44′ 12″	1° 22′ 46″
Hevelius	3′ 22″	6′ 8″	20′ 56″	31′ 54″	0° 44′ 4″	1° 22′ 12″

553 the table stands below the second, in one ruled frame, and fills the page to the foot. The first column carries the row labels and no heading, the last the units in italics as printed and no heading. Where a label reads only "True" [Vera. / Verum.], it is printed under the "Apparent" of the line above and belongs to the same quantity. The apparent angles are printed as two figures, minutes and seconds, given here as one value. In the last four rows each ratio is two figures joined by a printed rule, the Earth's figure first. In the ratio of the diameters for Kepler's hypothesis the page prints 11 before the rule, where the other ratios of this table print 1.

554

V. Table of the apparent diameter of the Earth, as if seen from the planets at their mean distance from it [V. TABULA APPARENTIS DIAMETRI TERRÆ Ex Planetis, mediocriter ab ipsâ diſtantibus quaſi ſpectatæ.]

Authors	From the Sun	From the Moon	From Saturn	From Jupiter	From Mars	From Venus	From Mercury
	Min. Sec.	*Gr. Mi. Se.*	*Min. Sec.*	*Min. Sec.*	*Min. Sec.*	*Min. Sec.*	*Min. Sec.*

555

From these it is abundantly clear that, even though the diameter of the Jovials appears, with respect to us, of small magnitude, namely of two seconds, and the Saturnian diameter of scarcely one second, their true diameter nevertheless runs, according to the Keplerian hypothesis, to 148, and according to ours even to 224 German miles; hence their solidity grows immensely. Considered from Jupiter, therefore, they are outstanding and very conspicuous bodies. For the first of the Jovials in order appears there, as regards apparent diameter, larger than the Moon, and indeed even than the Sun itself, appears to us. The diameter of each luminary is only 30′, more or less, whereas that of the first companion, seen from Jupiter, is estimated at 38′ 12″. The second in order, seen, that is, from Jupiter at 22′ 56″, is there scarcely a little smaller than the Moon itself is to us. The third Jovial, at a size of 14″ 20″, almost equals the Moon when halved [biſectam]. The fourth, because it amounts to 8′ 10″, sometimes even outdoes Venus at perigee. These things clearly show that Jupiter is a notable and splendid globe, accompanied by four Moons that continually undergo various changes, and indeed with so very swift a motion that the first Jovial goes round Jupiter in the space of 14 days, the second in 8, the third in 5, and the fourth in an interval of three days, whereas our Moon completes its period

554this table and the next stand in one ruled frame at the head of the page. The planets are printed in the column headings by their signs (♄, ♃, ♂, ♁, ♀, ☿), given here by name. The units, printed below the headings, are given in the second row in italics as printed; each value is printed as two or three figures, given here as one. The column "From the Earth" repeats the Sun's apparent diameters of the table of planetary sizes two pages earlier, except in Kepler's row, which there reads 30′ 0″.

555the title of this table is set inside the frame it shares with table IV. The Sun, the Moon and the planets are printed in the column headings by their signs (☉, ☽, ♄, ♃, ♂, ♀, ☿), given here by name. Units as printed in the second row, values given as one.

around the Earth only in a whole month. It is therefore most probable from this that far greater changes can occur at Jupiter than here with us by reason of the Moon.

[Margin: Quantæ magnitudinis Jovis Comites, ex Jove conſpecti.] *How large the companions of Jupiter are, seen from Jupiter.*

[Margin: Valde veriſimile eſſe videtur, Jovem longe majoribus mutationibus quàm noſtram Terram eſſe obnoxium.] *It seems very probable that Jupiter is subject to far greater changes than our Earth.*

The size of the apparent diameter of the orbit of each of the planets, if they are imagined to be seen from some fixed star, the parallax of the annual orbit being supposed a whole 10 seconds [Quantitas apparentis diametri Orbis ſingulorum planetarum, ſi ſinguntur conſpici ex aliquâ Stellâ fixâ,ſuppoſitâ parallaxi orbis annui integrâ 10 ſecundorum.]

	Proportions of the orbits		Apparent diameter
Of the fixed stars	41250.000	—	
Saturn	9.510	—	1′ 35″
Jupiter	5.200	—	0′ 52″
Mars	1.523	—	0′ 15″
Earth	1.000	—	0′ 10″
Venus	724	—	0′ 5″
Mercury	388	—	0′ 3″

556

557

Saturn's companion [Saturnalis], moreover, is likewise an outstanding planet. Its true diameter is 205 miles, while its apparent diameter, seen from Saturn, amounts to 19′ 6″; and it stands off from Saturn at almost as great an interval as that at which the Moon, for its part, nearly stands off from the Earth. Again, if the Moon were seen from Jupiter, its apparent diameter would scarcely be 12″, and from Saturn scarcely 6″. Indeed, believe me, the Sun itself would appear, from Jupiter itself, no larger than 6′ 8″, and from Saturn scarcely 3′ 22″, as is clear from table IV of the preceding ones. Add to this that those arms of Saturn, or attendants, clinging closely to its body, contribute not a little to this business.

[556] this table stands in its own ruled box to the right of the narrow column of text, its title inside the box. The planets are printed in the first column by their signs, given here by name; "Of the fixed stars" renders the printed "Fixarum". The figures of the second column are printed with a point in the first five rows and without one in the last two. Each row carries a printed rule between the proportion and the apparent diameter. The apparent diameters are printed as two figures, minutes and seconds, with the marks ′ and ″ printed only in the first row; given here as one value. At 10″ for the Earth's orbit, Venus's 724 and Mercury's 388 would give about 7″ and 4″, where the page prints 5 and 3.

[557] below the two tables the text is set in a narrow column on the left as far as "224 millia-", with the boxed table standing to its right; the sentence runs on below the box across the full width of the page. The prose is given here in one piece, and the boxed table after it.

[Margin: Quantus ſit Saturni Comes, ex Saturno viſus; quantumq́; ab eo diſtet.] *How large Saturn's companion is, seen from Saturn; and how far it stands from it.*

[Margin: Luna & Sol quantæ magnitudinis appareant ex Saturno & Jove.] *How large the Moon and the Sun appear from Saturn and Jupiter.*

Accordingly, there is no reason for us to wonder that so much matter and so many exhalations can, over the course of a longer time, be drawn out and exhaled, as much by the force of the Sun's rays as by that of the other bodies, from those seven primary [planets], as well as from the five lesser secondary ones and also from the two attendants of Saturn, that a comet can sometimes be generated from them. Above all, since not so much matter is required for such disc-shaped bodies as for wholly spherical ones. Rather, we certainly cannot help wondering how it can ever happen that from one single and so slender a body, namely our Earth, whose diameter seen from the other planets appears to be scarcely a few seconds, as the last of the preceding tables attests, and which is thus of almost no importance with respect to the other ethereal bodies, so great an abundance of exhalations and vapours can be cast out; from which, almost every day, as we know well from experience, so very many meteors are produced.

[Margin: Magis admirandum tot meteora exTerrâ, quàm ex tot corporibus Cœleſtibus nonnullos Cometas generari poſſe.] *It is more to be wondered at that so many meteors can be generated from the Earth than that some comets can be generated from so many celestial bodies.*

And although the Sun, as we touched on above, appears very slender to Saturn and Jupiter, so that, in your opinion, if I am not mistaken, the forces it can exert there in exhaling evaporations are also weak, the satellites of Jupiter and Saturn nonetheless make up for all of that no less vigorously; and above all that whole army of the fixed stars, all of which appear far larger and brighter on Saturn, Jupiter and Mars than here on the terrestrial globe. For the smallest of them all is seen there larger than Venus; but the larger ones, such as Arcturus, Capella, Lyra and Sirius, show at least 8′, 10′, indeed 12′ in diameter. For the fixed stars are immense bodies: the diameter of the smaller ones exceeds the Earth's diameter 1,006 times [millies ſexies], and that of the larger ones, namely of Sirius, 1,012 times [millies duodecies]; so that the solidity of this fixed star is greater than the solidity of the Earth by as much as this number, 15,056,882,800,000, indicates.

[Margin: Fixæ quantæ magnitudinis ex Saturno appareant, etiam reverà exiſtant ratione Terræ.] *How large the fixed stars appear from Saturn, and also how large they really are in relation to the Earth.*

Therefore, since the fixed stars, if searched out with the telescope, are almost innumerable, and moreover by far the most vast masses, there is surely no doubt that new stars are generated without difficulty from the exhalations of so very many fixed stars, and comets from the evaporations of the planets. Indeed, one is moved to wonder why more new stars do not arise. But perhaps a great

many are born which by no means come into view. For, as I conjecture, they rarely reach so great a size that they can be seen by us; *and many*, thus, *go by in secret* (as Seneca says in Book VII of the *Natural Questions*), *never rising before human eyes*. Without doubt many also rise every year, and set again, among the smallest ones, which are perceived only with the tube, especially in the Milky Way, where so many myriads of the tiniest stars occur; of these nothing whatever becomes known to the human race, nor can it ever even become known: for in no

[Margin: Posſe longè plures Cometas procreari, quàm quidem hactenus obſervati ſunt; & quare?] *That far more comets can be produced than have so far been observed; and why?*

[Margin: Ex minimis illisFixis ſæpiùs posſe nonnullas oriri ac rursùs occidere, quanquam nullus unquam id deprehenderit.] *That some of those smallest fixed stars can quite often rise and set again, although no one has ever detected it.*

way do we have them counted, as we do indeed have those more notable and larger ones, brought into tables through the most painstaking night-watches and the tireless study of the ancient astronomers. And yet, if one may confess the truth, a great many stars of the fourth, fifth and sixth magnitude are still missing from the globes, wholly neglected and omitted by our predecessors, and also by that supreme astronomer Tycho. Hence, however eagerly the mind strives to attend to new stars, it is nonetheless by no means free to do so, since we still by no means know all the old ones, even those clearly visible to the naked eye.

[Margin: Stellæ Fixæ neutiquam adhuc omnes in certum numerum relatæ ſunt.] *The fixed stars have by no means all yet been brought into a definite number.*

[Margin: Plurimæ veterum affixarum nondum hactenus obſervatæ fuerunt.] *Very many of the old fixed stars have not been observed up to now.*

It would therefore not be a vain labour, in our judgement, though a Herculean one, if all the fixed stars perceptible to the naked eye were observed correctly and in order, so that posterity could be certain of their true place as well as of their true magnitude and genuine colours, and so that it might in future be established with certainty whether some change also occurs with time, both in their number and in their magnitude and colours. Above all, so that it may not remain unknown whether some new little star arises, or whether some other, ancient one perishes. For I am almost convinced that very many new ones are not only kindled quite frequently among those smallest stars of the fifth and sixth magnitude, but also that some old ones change not a little in magnitude in the course of time, and indeed are sometimes extinguished entirely. Taking into account that many are now found not to be of so great a magnitude as Hipparchus and Ptolemy, those by far the most diligent observers, once established. Thus to the Bright Star of Aquila [Lucidæ Aquilæ], that remarkable star which at this time is rightly counted among the stars of the first rank, they assigned the second magnitude; the Bright Star of Aries they placed among the stars of the third magnitude, though it is now of the second; likewise

they made the Second of Aries equal to the First, namely of the fourth, although by the best right it is reckoned among the stars of the third magnitude and is much larger than that First of Aries. This is plain to anyone, to say nothing of the rest, a great many of which are found here and there differing very much indeed from the former standard and from the magnitude assigned to them. On the other hand, others occur which are now seen larger than formerly; among the rest, for example, the preceding star at the cheek of Cetus, which is only of the fourth magnitude, although the ancients recognised it as a star of the third magnitude; and many others of this kind are found, especially among those lesser ones of the fifth and sixth magnitude. Since this is wrongly ascribed to the carelessness of our predecessors, my mind foresees from it that some alteration lies hidden here. Indeed, since this is a matter of great moment, and it greatly concerns the philosopher who searches out heavenly things that this very point should at last be investigated accurately, I have therefore, with God's good help, undertaken this immense work. My intention, namely, was first to measure anew, in longitude and latitude, all those fixed stars which are contained in the catalogue of the ancients and also in Tycho's, but by an entirely new method, as exquisitely as can ever be done, with very large instruments made wholly of solid metal, six, seven, eight and more feet in size as regards the radius; then also to add all the remaining ones, not far below the sixth magnitude, which exist here and there in the heavens and have not yet been entered on globes or in any catalogue; and likewise to note down their magnitudes and colours with the utmost skill, to the best of my ability: so that posterity may at last not be ignorant whether and when some new [star]

[Margin: Valdè rei Aſtronomicæ conduceret, ſi Fixæ omnes nudis oculis deprehẽſibiles, recte obſerventur; & quare?] *It would greatly benefit astronomy if all the fixed stars perceptible to the naked eye were correctly observed; and why?*

[Margin: Nonnullas Fixas quà magnitudinem immutatas eſſe, exemplis & obſervationibus probatur.] *That some fixed stars have changed as regards magnitude is proved by examples and observations.*

[Margin: Cur Autor ſuſceperit cum DEO, novum &locupletiorem Fixarum Catalogum condere; & quidèm novâ ratione?] *Why the author has undertaken, with God, to compile a new and richer catalogue of the fixed stars; and that by a new method.*

comes forth, or whether [one] sets, and also whether they undergo some change. For very many changes in the heavens, *especially in the smaller stars, easily slip past through neglect of observations, and are lost to us*, as Verulam rightly judges, in the *Natur. & Univers. Philos.*, pages 126 and 148. If I learn that this labour will not be unwelcome to the learned, I shall take pains (since that task, with God's grace consenting, is already for the most part completed) that it be published shortly together with our *Machina coelestis*, provided that God, the Best and Greatest, most mercifully grants me life, health and leisure.

[Margin: MachinaCœleſtis Auctoris propediem prælo ſubjicietur.] *The author's Machina coelestis will shortly be put to the press.*

But let us continue on our way. And although we have already shown amply enough that so great a quantity of matter can certainly be evaporated and cast out from the fixed stars for some new star, and from the planets for a comet, I will nevertheless derive this still more clearly and demonstrate it as if with a finger, so that no lover of the truth will be able to retort anything at all in future: namely, that the Sun alone can belch forth and emit matter in so great an abundance as to be sufficient, not only after some years have passed for a single comet, but also for generating several, even supposing their diameters to be no smaller than the Moon's diameter; and that indeed in a very short space of time, namely of some months — what am I saying? — of weeks. So much so that in one year more matter is expired from the Sun than is needed to generate very many comets, however much each of them be supposed wholly equal to our most recent comet, of the year 1652, or to the one Seneca mentions in Book VII of the *Natural Questions*, with a diameter no smaller than the Sun's.

[Margin: Ex ſolo Sole plurimi Cometæ unico anno generari poſſunt.] *From the Sun alone very many comets can be generated in a single year.*

To begin with, from very many and by far most accurate observations of sunspots, Scheiner's as well as our own, we have learned abundantly that those spots appearing about the Sun are of different magnitudes: most of them amount to 1/40, 1/35, 1/30 part of the Sun's diameter; others in turn, namely the larger ones, equal 1/62, 1/12 and 1/18 part of the said diameter of the Sun. But the shadows and faculae are usually much larger as regards their diameter (the longer one, understand). For sometimes some tracts of shadows and faculae extend to 1/10, 1/7, 1/5, indeed to a third of the Sun's diameter (such as appeared in 1643 on July 20 and August 21, and were noted by us in the *Selenographia*). The nuclei, however, that is, the denser parts of the spots, quite often occupy one hundredth part, indeed one fiftieth, of the Sun's diameter; so that, to put it briefly, they are huge and wonderful bodies. Moreover, it almost surpasses human understanding how so much matter, and so many exhalations and vapours, could ever burst forth and be produced from that single body of the Sun, by which such very vast phenomena can be brought forth. The true diameter of their nuclei, when it is given as 1/50 part of the Sun's diameter and Kepler's distance of the Sun from the Earth is taken into account, turns out greater than the Moon's diameter; while the larger spots, equalling 1/18 part of the Sun's diameter, come close to almost the Earth's diameter, namely according to our distance of the Sun from the Earth; and this although you set the apparent diameter of the smaller spots at only a few seconds, and that of the larger at 1′ 47″.

[Margin: Quantæ m[[a/á]]gnitudinis reſpectu Solis ſint maculæ, faculæ, & umbræ Solares.] *How large the solar spots, faculae and shadows are in relation to the Sun.*

[Margin: Sunt immenſa, ac penitùs admiranda corpora.] *They are immense and wholly wonderful bodies.*

[Margin: Maculæ nonnullæ ratione diametri,Lunam & Terram excedunt.] *Some spots exceed the Moon and the Earth as regards diameter.*

But if these bodies, keeping the same magnitude, were placed in a location nearer the Earth, where comets sometimes travel — for example at only 110 semidiameters of the Earth, where the comet of the year 1652 stood at first; or somewhat closer still, where the comet of the year 1618 was seen on December 1 and 9, at 96 or 72 semidiameters of the Earth; but above all if they were set no farther off than the Moon, at 60 semidiameters of the Earth — O, by the immortal God, how wonderfully large these bodies would be as regards their apparent diameter! For a single nucleus containing 1/50 part of the Sun's diameter would equal the Moon at a distance of 110 semidiameters of the Earth, and at a remove of 60 semidiameters from the Earth would appear twice as large as the Moon. And those larger ones, taking up an eighteenth part of the Sun's diameter, would be seen at the former distance of 110 semidiameters of the Earth under an angle of 1° 24′ 26″, and at the latter, nearer elongation from the Earth under an angle of 2° 34′ 50″. Since all these things really are so (although to the Peripatetic school they may seem scarcely probable), they certainly deserve, as matters that open the doors to far more abstruse philosophical speculations, that whatever we have just said be computed correctly and accurately, and that it be clearly demonstrated to anyone both what the true diameter of the spots, faculae and nuclei is for those distinct magnitudes, and also how great their area of the great circle is, together with the apparent diameter at various distances below the Sun.

[Margin: Quâ facie, & magnitudine maculæSolares apparerent, ſi nobis viciniores, ad diſtantiam ſc. Lunæ, darentur.] *With what appearance and size the sunspots would appear if they were set nearer to us, namely at the distance of the Moon.*

[Margin: Magnitudo apparentis diametri Macularum in diverſis àTerrâ diſtantiis, in Tabellâ exhibita.] *The size of the apparent diameter of the spots at various distances from the Earth, shown in a little table.*

For the good of philosophy, I have entered all this in the following little table, leaving out entirely all the lengthy and most tedious calculation, according both to Kepler's and to our own mean distance of the Sun from the Earth. In the first column you will have the ratio of the spots, nuclei and shadows to the Sun's diameter; in the second column the apparent diameter of the spots, in minutes and seconds; in the third the true diameter; in the fourth the area of the circular disc; and in the four following the apparent diameter at various distances, namely according to Kepler's hypothesis. Lastly, in the remaining ones, all these are shown according to our own [hypothesis].

	Ratio of the diameter of the spots to the Sun's diameter	Apparent diameter of the sunspot	True diameter of the sunspots	Area of the circular disc, or of the great circle	At 60 semidiameters of the Earth	At 72 semidiameters of the Earth	At 96 semidiameters of the Earth	At 110 semidiameters of the Earth

558

[558] the table stands below the prose in one ruled frame, with no title of its own. The first column carries the row labels and no heading. The columns from the true diameter onward stand under the heading "At the mean distance of the Sun from the Earth of 3410 semidiameters of the Earth, according to Kepler's hypothesis" [Ad diſtantiam Solis à Terrâ Mediam 3410 Semid.Terræ. Juxta Hypoth. Kepler.]; the box above the first three columns is empty. The last four columns stand under the further heading "Apparent diameters of the spots, if their distance from the Earth is set at" [Diametri Apparentes Macular. ſi ſtatuatur ipſarum diſtantia à Terrâ.], each column then headed by its distance, printed "60 S.T.", "72 S.T.", "96 S.T." and "110 S.T.". The Sun is printed in the second and third headings by its sign. The units, printed below the headings, are given in the second row in italics as printed; each value printed as two or three figures is given here as one. The ratio is printed as 1, a long rule and the denominator. Rules divide the rows into four groups of three. No label row stands below the last row of figures.

	Ratio of the diameter of the spots to the Sun's diameter	Apparent diameter of the sunspot	True diameter of the sunspots	Area of the circular disc of the spots	At 60 semidiameters of the Earth	At 72 semidiameters of the Earth	At 96 semidiameters of the Earth	At 110 semidiameters of the Earth

559

You will therefore understand, with hardly any trouble, how admirable and astonishing a magnitude these very bodies display. The most common of them, which take up one fortieth part of the Sun's diameter, contain 1032 German miles in true diameter; that is, they are twice as large as the Moon's diameter. The diameter of the larger ones, however, comes to 2324 German miles, and so they exceed the diameter of the Earth. Further, those tracts of shadows and faculae: their length is sometimes eight times greater than the Earth's.

[Margin: Quanta ſit vera diameter minorum & majorum Macularum Solarium.] *How great the true diameter of the smaller and the larger sunspots is.*

Therefore all the more judicious philosophers will admit with me that an almost incredible abundance of exhalations and of smoky evaporations is needed to generate bodies of this kind, as is plain from the table. Now the Sun alone is able to supply from its own body so much matter for producing such vast phenomena; indeed, perhaps it casts out of its innards much more matter still than it has so far been granted us to know or to observe. Certainly countless faculae, shadows and spots are, without any doubt, generated and corrupted again which never come into our view, however watchful we are in directing and fixing our eyes on them at all times: both because the sky is quite often cloudy, and because of the rarity of the matter. Above all, how many spots are generated in the hidden hemisphere of the Sun, and are destroyed there again, before they reach our visible horizon and rise for us? — to say nothing of the case if all the fainter and smaller spots, faculae and secondary shadows, which wholly escape the sight, were to be taken into account here. So it is beyond doubt that the Sun is indeed still expiring a great deal of matter day by day, while we are quite unaware and unsuspecting.

[Margin: Immensâ fumidarum evaporationum copiâ, ad componendas maculas opus eſt.] *An immense abundance of smoky evaporations is needed to compose the spots.*

---

559 the table heads the page, above the prose, in one ruled frame, with no title of its own; it continues the series of the preceding page's table. The first column carries the row labels and no heading. The columns from the true diameter onward stand under the heading "At the mean distance of the Sun from the Earth of 5160 semidiameters of the Earth" [Ad diſtantiam Solis à Terrâ Mediam 5160 Semid. Terræ.]; the box above the first three columns is empty. The last four columns stand under the further heading "Apparent diameters of the spots, if their distance from the Earth is set at" [Diametri Apparentes Macular. ſi ſtatuatur / ipſarum diſtantia à Terrâ.], in which a short oblique stroke of unclear function stands before "ipſarum"; each column is then headed by its distance, printed "60 S.T.", "72 S.T.", "96 S.T." and "110 S.T.". The Sun is printed in the second and third headings by its sign. The units, printed below the headings, are given in the second row in italics as printed; each value printed as two or three figures is given here as one. The ratio is printed as 1, a long rule and the denominator. Rules divide the rows into four groups of three. No label row stands below the last row of figures.

[Margin: Sol adhuc longè plùs materiarum & effluviorum exſpirat, quàm unquam nobis obſervare datur.] *The Sun expires far more matter and effluvia still than it is ever granted us to observe.*

For the rest, what, I ask, do you think: how great a quantity of effluvia does the Sun hurl out every year and every month? But you will perhaps be amazed that I am not afraid to pronounce something certain on this matter — and indeed on such utterly abstruse things, so very remote from our senses; without doubt you are convinced that there is need of a greater en-

[Margin: Quantum evaporationum, & halituum Sol ſingulis annis ejiciat.] *How much in evaporations and vapours the Sun casts out each year.*

deavour than was Archimedes', when he inquired how great the number of grains of sand would be with which the whole world, or one ten times larger, would be filled. But although that very task was somewhat laborious for Archimedes, it was nevertheless not in vain; so too this, which we have now set ourselves to investigate, will, I hope, with the divine Power favouring it, turn out happily, and indeed more quickly.

[Margin: Hæc quæſtio ferè ſimilis illi Archimedeæ de numero arenæ videtur.] *This question seems almost similar to that Archimedean one on the number of the sand.*

First, then, observations plainly show that sometimes, even in the course of a single year, a hundred, indeed two hundred spots have appeared in the visible hemisphere of the Sun, apart from all those which, because of their thinness, eluded the keenness of the eyes, or lay hidden in the other, concealed hemisphere of the Sun. Yet they were not all found to be of entirely equal size. Some, the very smallest, took up scarcely 1/300 or 1/200 part of the Sun's diameter; others again, somewhat larger, subtended 1/30, 1/25, 1/20, indeed 1/18 part of the Sun's disc — to say nothing of all those faculae and shadows that arose together with the spots themselves, which certainly possessed twice as much matter as all the spots visible during that whole year. But be that as it may, let us freely pass over the faculae and shadows, lest we seem to do violence to the attempt; and this time let us set before everyone's eyes only those spots which we ourselves observed in the Sun in the years 1643 and 1644.

[Margin: Quot & quales maculæ uno anno aliquando in diſco Solis animadverſæ fuerint.] *How many spots, and of what kind, have sometimes been observed in the Sun's disc in one year.*

When all of these, as presented in the *Selenographia*, are well considered, you will find — especially if you take a middle course, somewhat reducing the larger ones of 1/20 and 1/18 of the Sun's diameter and slightly increasing the smaller ones — that one can without injustice, on this condition, count forty spots and assume them to be visible in a single year, all of them taking up at least 1/50 part of the Sun's diameter.

[Margin: Quot maculas Autor uno anno deprehenderit.] *How many spots the author detected in one year.*

If each of these is subjected to calculation, and the area of the great circle of those spots is properly computed — as can very easily be done, since the area of a single spot of 1/50 part has already been shown in the preceding table — that is, by multiplying that same area of 525,500 German miles by 40 spots, the product will be the whole matter of these 40 spots, namely 21,020,000 in cubic miles. This number, divided by the area of the circle or disc of the Moon, gives a quotient of about 137. And so many phenomena, I say, can be produced from the solar vapours in the space of one year, wholly equal to the lunar disc as regards diameter; while to the terrestrial [disc], no fewer than 9 1/19; indeed 39 1/5 comets, entirely similar, namely as regards the area of the great circle, to the one existing in the year 1652, would be created from the same matter, so that the thickness came to a German mile; and moreover they would have the same thickness as the larger sunspots — which spots, believe me, are for the most part thicker than the comets themselves, as it would not be difficult to prove more fully, if paper were not to be spared.

[Margin: Quot phænomena Lunæ Terræq; quoad diſcum æqualia Sol unico anno progignere queat.] *How many phenomena equal to the Moon and the Earth as regards the disc the Sun can produce in a single year.*

From this it is now clearly proved how great a mass of matter and of exhalations can be exhaled from the body of the Sun alone, so that in the course of a single year it is possible, as we were just saying, for very many comets to be generated. But truly, granting that only 20 spots of the above-mentioned size of 1/50 part of the Sun's diameter were born in one year (even if in the years 1643 and 1644 many more spots existed, while all the remaining fainter ones, the faculae and the shadows, which by their bulk surpassed even 100 spots, are left wholly out of account), nevertheless 68 comets to the lunar disc, and 4 1/2 to the terrestrial; indeed, to the comet of the year 1652, 19 6/10 entirely equ-

[Margin: Quot igitur Cometæ ex Solari materiâ uno anno coagulari poſſint ?] *How many comets, then, can be congealed from solar matter in one year?*

al, can be congealed from so great a quantity of the matter of the spots — every single year, that is. I put this forward, however, so that you may understand that I have in no way done violence to this argument of ours, and at the same time so that it may become the more clearly known that even from the Sun itself alone much more matter flows out and boils up than suffices for comets — let alone that remarkable comets can sometimes come forth from all the planets together, of which 12 have now become known.

Indeed, if we examine the matter still more carefully, it will be shown, and not obscurely, that in certain years a far greater abundance of expirations still has flowed out of the Sun than we have in fact assumed. For in the year 1625, on the testimony of Scheiner in the *Rosa Ursina*, far more frequent spots were observed in the Sun than in the years 1643 and 1644 — some hundreds, that is, if account is taken of them all. Of the principal ones alone, which the author named above marked with letters, there were 153 in number, although he sometimes took four and five for a single one. When these are properly

considered as a whole, they can rightly be taken for 100 spots taking up 1/50 part of the Sun's diameter. And with the calculation set up in this way, it is clearly established that from that same matter there could have been formed 342 comets not inferior to the Moon's disc, and 23 to the Earth's, while 98 were not inferior to the comet of our year 1652 (as regards size, that is) — even leaving out of account all those shadows, clouds and faculae that appeared together in abundance in the same year.

[Margin: Quot maculæ anno 1625 in Sole conſpectæ fuerunt.] *How many spots were seen in the Sun in the year 1625.*

[Margin: Quot Cometæ ex iſtis maculis iſto anno potuisſent generari.] *How many comets could have been generated from those spots in that year.*

Meanwhile, however, I would have you know that the Sun does not exhale equally many spots every year, but more at one time than at another; just as it also happens to our Earth in exhaling vapours that at different times of the year it fosters more frequent clouds, rains, snows and other meteors. But when such a barrenness occurs in those denser effluxions from which the spots are consolidated, it may be that then — so far as one may divine by conjecture — far more of the thinner exhalations are cast out of the Sun to form comets. Yet these are not always so packed together and gathered, or joined with the effluvia of other planets, that they plainly meet the eyes of all.

[Margin: Non ſingulis annis æq́; multùm materiæ, Sol ex corpore ſuo evomit.] *The Sun does not vomit forth equally much matter from its body every year.*

In sum, we think we have shown more than sufficiently how many vapours and exhalations the Sun alone can vomit forth. For sometimes, when a remarkable fertility befalls it (since at fixed times it too undergoes its own stimulations and exacerbations, as happened in the year 1625), the Sun is able to cast out and exhale in one year so great an abundance of matter and of expirations that it can produce 8 comets every month — that is, two every week — wholly equal, as regards the disc, to that [comet] of the year 1652; indeed, nearly one equal to the Moon every day, as the calculation shows. Therefore, since the single body of the Sun produces so many exhalations and evaporations in the space of one year, how many, I ask, will all the planets together supply over an interval of, at times, many years? Since this is entirely so, I cannot wonder enough, again and again, how it ever happens that comets are not more frequent, since sufficient matter wanders here and there through the whole aether. But perhaps very many are unobservable because of the rarity of their matter, the thinness of their body and their excessive distance, so that they vanish too soon, before they come into view.

[Margin: Immenſam itaq́; evaporationum copiam Solem exhalare, etiam nonnunquam ad innumeros Cometas producendos, apertè demonſtratur.] *It is thus plainly shown that the Sun exhales an immense abundance of evaporations, sometimes even for producing innumerable comets.*

[Margin: Autor iterum iterumq́; demiratur non plures Cometas ſub adſpectum nobis cadere.] *The author wonders again and again that more comets do not come into our view.*

From this, further, one can recognize how immense an abundance of matter all the fixed stars, each and every one — so innumerable, and bodies so very vast, far exceeding the planets in bulk — are able to cast out and exhale. Likewise, it is no wonder that in the course of time one or another new star meeting our eyes can be generated from it; but it is most probable that a great many smaller new ones, which wholly escape the keenness of the eyes, are brought forth rather often in the system of the fixed stars.

[Margin: Non abſonum eſt perplures novas Stellas tractu temporis exoriri poſſe.] *It is not absurd that very many new stars can arise in the course of time.*

Finally, from this rather lengthy discussion of ours above, anyone now [?] also understands without difficulty that, although the ethereal bodies constantly expire and emit effluvia and perpetually belch forth much matter, nevertheless nothing whatever is lost to those bodies, nor do they suffer any decrease or detriment from it. For just as the Sun, as has been most evidently demonstrated, continually casts out effluxions and evaporations — and indeed in such abundance that so very many bodies, far the vastest, can be congealed from them in a short space of time without any detriment to its own body — so it is arranged in the same way with the remaining bodies of the planets, so that they are by no means changed on that account, much less diminished. For even if at one time they exhale exhalations, at another time in turn they recall them and draw them back, so that nothing but a certain circulation of nature, or as it were a flux and reflux of evaporations and expirations, takes place in those bodies. And so whatever is lost to them at one time is added to them again at another, so that they always persist firmly in the same course and in an unvaried state as regards the whole, just as they were created in the beginning.

[Margin: Clarè oſtenditur, licet corpora ætherea immane quantum exhalationum ejaculentur,nihil tamen prorsùs illis decedere.] *It is clearly shown that, although the ethereal bodies hurl out an enormous quantity of exhalations, nothing at all is lost to them.*

Empty, therefore, is the fear that the celestial bodies, because of the alteration of their parts, will at last dissolve and perish; and vain too is the superstition that the aether is subject to no generations and corruptions at all. For, as has been urged more than once, the celestial generations, mutations, alterations and corruptions are far more remarkable and greater than the sublunary ones. Admittedly, if each and every exhalation and evaporation that our Earth daily thrusts out all around into the atmosphere and expires, and from which clouds and other meteors are produced in the sublunary air, could be counted, the abundance of effluvia would likewise be huge, believe me — perhaps even greater than you would ever have imagined. But be that as it may, in comparison with the celestial expirations they come into no consideration at all.

[Margin: Metuunt quidem Antagoniſtæ, ne corpora Cœleſtia diffluant; ſed fruſtrà.] *The opponents do fear that the celestial bodies may dissolve; but in vain.*

Lastly, since so very many exhalations wander through the whole ethereal air, it is rightly asked whether they meet our eyes and produce for us some parallax, or refraction. By no means, certainly. For since those most abundant solar effluxions, clinging almost perpetually about the Sun, are in no way perceived by the naked eye, and, so far as one can judge, do not cloud the Sun itself in any way, how, I ask, will you notice them in the remaining planets, bodies so much more remote and smaller? Their effluxions are for the most part so very thin that they wholly escape all sight; and besides, they are dispersed so sparsely through the whole aether as far as the fixed stars that they can by no means be grasped by the senses. Indeed, although a tract of exhalations, huge in itself, may cling here and there, the matter is nevertheless of no account at all, if the most ample

[Margin: Utrumne evaporationes æthereæ refractionem aliquam inducant ?] *Whether the ethereal evaporations induce any refraction.*

field in which they dwell. For there they rarely present a magnitude of one or two seconds; and how, I ask you to judge for yourself, could so very small a thing ever be noticed in that most vast system of the world, whose diameter, computed in semidiameters of the Earth, contains 150,000,000; its circumference 471,000,000; its concave surface 70,800,000,000,000,000; and its solid content 1,767,000,000,000,000,000,000,000 semidiameters of the Earth? Will it not vanish altogether and withdraw itself entirely from our senses? So it would happen with terrestrial clouds, if they were viewed from the planets, let alone from the fixed stars. But enough of these matters.

[Margin: Magnitudo, & vaſtitas totius Mundi Syſtematis.] *The magnitude and vastness of the whole system of the world.*

Now the order of the work seems to require that we turn to the remaining questions. But it will serve our purpose better if, before we come to them, we first treat somewhat more fully and specifically of the generation of comets — namely of their first rising, increase, decrease and destruction — and then illustrate all of it with certain figures, as accurately as can be done. For discussing this matter, the generation and corruption of the solar spots will certainly contribute not a little. For surely nothing in the whole machine of the world is so joined to comets in its affections and properties, and agrees with them so exactly in most respects, as the said solar spots. We have indeed already stated this in part at the beginning of this book; but since it was not yet developed there as far as would suffice, nor could it be done at such length, we shall therefore discharge it the more amply now. Before we may come down to that, however, it will be worthwhile to set before everyone's eyes in advance the properties and the very nature of the solar spots — namely how they are generated and dispersed again, and whatever is most worth noting in the same matter (since comets enjoy almost entirely similar properties). This will not only do much toward a fuller and easier understanding of this subject; it will also allow us

hereafter to argue correctly that what happens in the Sun and its evaporations and effluxions is no less likely to be able to happen in the remaining bodies too, and in comets as well, which exist in the same medium, or aether. Moreover, since we see that comets agree with the spots in most respects as regards their rising and destruction, [it will allow us to argue] that it is not absurd [that they] are likewise akin to the same spots in those remaining respects that are not so plainly grasped. Nor do such inferences displease Aristotle himself, since he holds that one must judge of remote things according to the way near things are, and that similar effects point to similar causes. Since, therefore, the solar spots evidently show the manner of the generation of the ethereal bodies, it will certainly also be easy for anyone to perceive how the generation of comets comes about, and then how matters stand in this business with the remaining phenomena.

[Margin: Maculæ Solares cum Cometis, ratione proprietatum, & affectionum, valdè conveniunt.] *The solar spots agree closely with comets in respect of their properties and affections.*

[Margin: Maculæ multùm luminis Cometis conferunt, inprimis ratione generationis.] *The spots shed much light on comets, especially in respect of their generation.*

But to approach the matter itself, it will be necessary to recall to memory once more that the spots themselves are ethereal bodies, and very near the Sun, as has been abundantly shown in the *Rosa Ursina* and in the *Selenographia*. If these do not yet satisfy someone, let him make observations himself: he will find by experience that the matter is entirely so. But what properties the spots enjoy besides, both in

[Margin: SuccinctaMacularum Solarium deſcriptio.] *A concise description of the solar spots.*

their first rising and in their whole duration and destruction, must now be told somewhat more fully. Although this is a very lengthy business, nevertheless, so as not to be too burdensome to the kind reader, I shall aim at brevity and gather everything that seems to bear on it into certain definite assertions and aphorisms. Just as these, certainly, rest on undoubted observations of many years, Scheiner's as well as our own, so they can also be demonstrated to anyone at any time by daily observations.

1. The solar spots have a twofold rising and setting, physical and astronomical. The physical is when they really are born and perish; the astronomical, when they seem to enter and leave the visible hemisphere.

[Margin: Ortus Phyſicus, & Aſtronomicus Macularum Solarium.] *The physical and the astronomical rising of the solar spots.*

2. They are generated at every time of the year, not far from the Sun, out of a most thin matter, at first entirely imperceptible to us, belched forth and evaporated from the Sun itself — or out of solar vapours and exhalations. Then they grow, and either remain for some time on the disc of the Sun, or are moved by reason of the Sun's rotation. Afterwards they decrease

again little by little, are at last dissolved, and pass into the most thin ethereal air.

[Margin: Quando generentur; an creſcant, & decreſcant ?] *When they are generated; whether they grow and decrease.*

3. They have a threefold time — of increase, of standing, and of decrease — and this is to be taken both optically and physically.
4. Physical increase and decrease do not belong to any one particular region of the Sun, as optical dilatation and contraction do; rather, they take place in any part of the Sun whatever, and indeed successively, yet gradually and unequally. Hence it happens that a spot which grows slowly and lasts long sometimes fails quickly; and in turn, one that springs up quickly lasts long, and at last is extinguished slowly and gradually. Sometimes one is enlarged quickly, grows faster than one would expect, and condenses; it decreases in the same way and is resolved into shadows. Another, on the contrary, [does so] very slowly.

[Margin: De augmento & decremento Macularum Phyſico.] *On the physical increase and decrease of the spots.*

5. The spots are begotten and increased by the concourse of like matter to like, by condensation, by adgeneration, by substantial generation, and by the aggregation of several very small spots; and in the contrary way, in turn, they are diminished, resolved, and perish.

[Margin: Quomodo procreentur.] *How they are produced.*

6. The spots are not spherical bodies but extended, flat ones, though of varying thickness, presenting sometimes regular figures, mostly round, and sometimes irregular figures of any kind. For near the Sun's horizon the spots grow slender, while near its centre they appear broader and more extended; but this could not happen if they were spherical bodies. For every spherical body always appears with the same round face, whether you view it under direct or under oblique rays, as is clear from optics.

[Margin: An corpora omninò ſint ſphærica ?] *Whether they are spherical bodies at all.*

7. The spots are extremely diverse and unequal, as much in figure, size, thickness and depth as in colour, darkness, density and rarity.
8. Just as not all of them are uniform throughout in darkness and density, nor in colour either, but the greatest part of the spots consists of diverse parts, rarer and more opaque, so too they sometimes possess nuclei of the most diverse thickness, density and colour, as can usually be seen in those larger spots.

[Margin: Sunt inæquales figurâ, denſitate & colore.] *They are unequal in figure, density and colour.*

9. The nuclei, like the spots themselves that are uniform and simple — that is, without nuclei — and consist of [?] uniform and equally dense matter, grow and decrease. Gradually they become large [?] small, and in the same way from large they become small. Moreover, those that do not

last [?] long usually grow and diminish very quickly; but those that grow large [?] gradually also persist longer.

[Margin: Nuclei Macularum, an augeantur & deminuantur ?] *The nuclei of the spots: whether they are increased and diminished.*

10. The nuclei, just like the spots themselves, quite often arise out of shadows and faculae, and out of the smallest [?] ones; and out of many they coalesce little by little — indeed fairly quickly — so [?] that not rarely one is born out of many separate nuclei, and in turn out of one there are sometimes born two [?], three or more.
11. The nuclei do not always stand precisely in the middle of the spot; rather, they now and then decline to the sides [?], and quite often they draw some thinner mass after them.

[Margin: Nuclei, num centrum ſemper in maculis obtineant ?] *The nuclei: whether they always hold the centre in the spots.*

12. The nuclei, like the spots, grow and darken [?] from the inflow of matter and from condensation; conversely, from the outflow of matter and from rarefaction they become paler and whiten [?].
13. Every spot endowed with a nucleus, whether one or several, is clothed [?] round with some other body, less dark and rarer, so that it is surrounded by a peculiar atmosphere [?], as it were, sometimes rarer, sometimes denser. This shines out plainly from that [?] halo and rainbow by which they are sometimes girded.

[Margin: Nuclei habent ſuas atmoſphæras.] *The nuclei have their own atmospheres.*

14. No nucleus is observed to be born physically at the same time as its spot; [?] no spot sets whose nucleus does not first fail gradually, so that the more solid [?] and denser parts suffer dissolution sooner than the thinner ones.

[Margin: Tardiùs Nucleus naſcitur, & rursùs citiùs evaneſcit, quàm reliqua macularum materia.] *The nucleus is born later, and in turn vanishes sooner, than the rest of the matter of the spots.*

15. Neither the spots nor the nuclei are generated or corrupted always in the same [?] place. In longitude they are generated over the whole disc of the Sun without distinction [?]; in latitude, however, they have a peculiar zodiac and fixed limits [?], within which they usually carry on these changes, alterations and vicissitudes. But around the polar parts of the Sun nothing but very thin secondary spots is seen [?]. The reason is this: the motion of the Sun and of its atmosphere around the ecliptic and the intermediate parts — namely the torrid zone — is more vigorous, and consequently its power is more lively.

[Margin: Maculæ habent peculiaremZodiacum.] *The spots have a peculiar zodiac.*

16. The spots and nuclei, and the faculae as well, are some longer-lasting than others by reason of their underlying matter [?]. Some first rise near

the eastern limb of the Sun and vanish in the middle [?] of the disc after a few days; some are born in the middle of the disc and perish near [?] the Sun's western horizon; some, more solid and more opaque, travel across the whole [?] disc of the Sun, sometimes growing, compacting and condensing [?] themselves, sometimes decreasing, thinning and rarefying themselves. Some remain in their state for a long time [?], so that they not only pass once across the visible hemisphere of the Sun, but [?] also across the whole hidden one, and come forth [?] again a second time above the eastern horizon and persist there for some time. But they very rarely return a third time — indeed almost [?] never (as far as I have observed). For that matter is at last scattered and resolved into the thinnest ethereal air. Hence some spots are seen without an astronomical rising, and some without an astronomical rising and setting; others too are seen in the visible hemisphere [?] without a physical rising and setting. And so none endures for ever, but at last vanishes, and others arise in their own time when new matter is supplied.

[Margin: Aliæ aliis ſunt diuturniores,& ſolidiores.] *Some are longer-lasting and more solid than others.*

[Margin: Nonnullæ Maculæ quoties redeant.] *How often some spots return.*

17. Two spots often appear equal at the beginning, both in matter and in size and consistency; and yet they perish not at the same time, but at a different time and place.

[Margin: Non omnes ſimul intereunt.] *Not all perish at the same time.*

18. Every spot consists of opaque, dense and blackish matter; the light it possesses, however, it draws from the Sun, and it enjoys no light of its own.

[Margin: Lumen ex Sole hauriunt.] *They draw their light from the Sun.*

19. The spots are larger than they appear. For since they are far smaller than the Sun, the illuminating body, they are therefore illuminated over more than half [their surface], like the Moon.

[Margin: Sunt opinione majores.] *They are larger than one supposes.*

20. No spots revolve about an axis; rather, with an even course, always keeping the same face where they face the Sun and the Earth, they are carried round the centre of the Sun, like terrestrial clouds. For no spot grows slender near the centre.

[Margin: An maculæ circa axem circumgyrentur ?] *Whether the spots turn about an axis.*

21. The spots move across the disc of the Sun regularly, but in different ways at different times of the year: sometimes in a straight line, sometimes in a circular — or rather an elliptical — one. The concavity of this section, and sometimes its convexity, faces the ecliptic, though at a differing inclination. This motion does not belong to the spots as their own; it belongs to the Sun, or rather to the Earth, and depends on the Earth's annual motion, if the matter is weighed accurately. That the spots seem

to advance more slowly on one day or another, however, is to be ascribed to their own natural motion, which as it were resists and opposes the regular rotatory motion of the Sun.

[Margin: Regulari quidem,ſed ſingulis menſibus, diverſo motu, in univerſum moventur.] *On the whole they are moved with a regular motion indeed, but with a different one in each month.*

22. They move continuously, and indeed uniformly with respect to the Sun, but unequally in appearance. Hence in the middle of the disc the daily motion seems swifter and greater, and near the horizons slower and smaller; and the nearer they stand to the horizon, or limb, the tighter, narrower and smaller the space of their journey — that is, their daily space — that they complete, by reason of their more oblique position and aspect.

[Margin: Motus macularum apparens eſt inæqualis.] *The apparent motion of the spots is unequal.*

23. The spots also possess a proper motion of their own, but one perpetually irregular and anomalous. Hence those corpuscles and nuclei of which the whole spot consists move in different ways with respect to one another: they approach and recede, are joined and separated, gathered and dispersed. And from this arise the sudden coalitions of the spots, their abrupt digressions, their disordered deviations, and the perpetual transformations of their figures.

[Margin: Motus illarum proprius pariter eſt anomalus.] *Their proper motion is likewise anomalous.*

24. Although the spots are bodies of wonderful size — so that some sometimes exceed the diameter and disc of the Moon, indeed of the Earth — they nevertheless do not exhaust the Sun, nor does the Sun suffer any decrease from them. For when the matter is dissolved and attenuated, the Sun in turn draws it back and receives it, as the Earth does its vapours and exhalations.

[Margin: Quantæ ſint magnitudinis.] *How large they are.*

25. The spots of the Sun are not equidistant from the surface of the Sun; some are more remote than others. Yet none is so far removed from the Sun that it could suffer any sensible parallax.

[Margin: Quamvis non æquali à Sole removeantur interſtitio;nullam tamen parall. patiuntur.] *Although they are removed from the Sun by an unequal interval, they nevertheless suffer no parallax.*

26. The Sun does not always nourish spots on its disc; sometimes it is entirely free of every primary spot and of the more notable shadows and faculae, so that sometimes for a space of several months hardly anything worth noting is found on the disc of the Sun.

[Margin: Nonnunquam Sol ab omni maculâ prorsùs liber eſt.] *Sometimes the Sun is entirely free of every spot.*

Diagram. Engraved folding plate, "Fig. D.", of which this page shows the left part; the rest of the same plate is the next page. Eight rows of drawings of spots run across the plate, each row headed at the right by a two-line caption that begins with its Roman number, I to VIII: "Facies Macularum …" *Appearance of the spots …*, then "Anno 1625, à Die …" *in the year 1625, from the day …*. Under each caption the drawings stand in a line, each with an engraved number above it and one or more small letters beside it. The spots are drawn as hatched dark cores, many of them inside dotted or lightly hatched outlines, some as scattered clusters of small dots. Near the right edge of this part a vertical fold crosses the whole plate; beyond it only a narrow strip of the next panel shows. Every caption runs into the fold and on beyond the edge of this part, so the end of each caption is not read here. "Fig. D." stands at lower left. All labels on this part of the plate are listed below; none is supplied from the text.

- Row I. Caption: "I Facies Macularum" *I. Appearance of the spots*, followed by a word beginning with S, broken by the fold [?]; "Anno 1625, à Die" *in the year 1625, from the day* [?] February [?]. Drawings: *10*; *11*, with *b*; *12*, with *c* and *b*; *14*, with *c* and *b*; *15*, with *c*.
- Row II. Caption: "II Facies" *II. Appearance of the spots* [?]; "Anno 1625," *in the year 1625*, [?] *day* [?]. Drawings: *23*, *24*, *25*, *26*, *27*, each with *c*; *28* (beyond the fold).
- Row III. Caption: "III Facies Macularum" *III. Appearance of the spots* [?]; "Anno 1625, à" *in the year 1625, from the d[ay]* [?] *11* [?]. Drawings: *11*, *12*, *13*, *14*, *15*, each with *a*; *16* (beyond the fold).
- Row IV. Caption: "IV Facies Macularum" *IV. Appearance of the spots*, followed by a word beginning with S, broken by the fold [?]; "Anno 1625, à Die" *in the year 1625, from the day* [?] June [?]. Drawings: *8*, *9*, *10*, *11*, *12*, *13*, each with *k*.
- Row V. Caption: "V Facies Macularum" *V. Appearance of the spots* [?]; "Anno 1625, à Die 1" *in the year 1625, from the day 1* [?] July [?]. Drawings: *12*, *13*, *14*, *15*, *16*, each with a small oval that may be the letter *o* or a cipher [?].
- Row VI. Caption: "VI Facies Macularum" *VI. Appearance of the spots* [?]; "Anno 1625, à 7" *in the year 1625, from the 7th* [?]. Drawings: *7*, *8*, *9*, *10*, *11*, each with *a*.
- Row VII. Caption: "VII Facies Macularum" *VII. Appearance of the spots* [?]; "Anno 1625, à 18" *in the year 1625, from the 18th* [of Au]gust [?]. Drawings: *18*, *19*, *20*, each with *a*; *21*, with a small mark that may be *a* or *o* [?]; then *a*; *22*; a number beginning with 2, cut by the fold [?]; *a*.
- Row VIII. Caption: "VIII Facies Macularum" *VIII. Appearance of the spots* [?]; *in the year 162*[?], *from the day* [?]. Drawings: *31*, *1*, *2*, *3*, *4*, each with *c*; *5*, with *c* (beyond the fold).
- Lower left: "Fig. D."

Fig. D, right part. This page shows the right part of the same folding plate Fig. D described on the previous page: a narrow strip of the left part, the fold,

and then the rest of the eight rows, each caption running on from the left part. All labels on this part of the plate are listed below; none is supplied from the text.

- Row I. Caption, continued: "rium obſervata Romæ," *solar [?], observed at Rome*; "10Febr. ad 21 ejusdem." *10 February, to the 21st of the same [month]*. Drawings: *5* (the end of 15, at the fold); a drawing with *b*, its number not on this part; *17*, with *c* and *b*; *19*, with *c* and *b*; *20*, with *c* and *b*; *21*.
- Row II. Caption, continued: "Solarium obſervata Romæ," *solar, observed at Rome*; "Die 23 Martii, ad 3 Apr." *…25,* [?] *the day 23 March, to 3 April*. Drawings: *28*, *29*, *30*, *31*, *1*, *2*, *3*, each with *c*.
- Row III. Caption, continued: "larium obſervata Romæ," *solar [?], observed at Rome*; "1 Maji, ad 22 ejusdem." *day* [?] *1 May, to the 22nd of the same [month]*. Drawings: *16*, *17*, *18*, *19*, *20*, *22*, each with *a*.
- Row IV. Caption, continued: "rium obſervata Romæ," *solar [?], observed at Rome*; "unii, ad 18 ejusdem." *8 June [?], to the 18th of the same [month]*. Drawings: a *k* before the fold (beside the drawing numbered 13 on the left part); *14*, *15*, *16*, *17*, *18*, each with *k*.
- Row V. Caption, continued: "rium obſervata Romæ," *solar [?], observed at Rome*; "ulii, ad 22 ejusdem." *12 July [?], to the 22nd of the same [month]*. Drawings: *17*, *18*, *19*, *20*, *22*, each with a small oval that may be the letter *o* or a cipher [?].
- Row VI. Caption, continued: "arium obſervata Romæ," *solar [?], observed at Rome*; "sti, ad 17 ejusdem." *August [?], to the 17th of the same [month]*. Drawings: *12*, *13*, *14*, *15*, *16*, *17*, each with *a*.
- Row VII. Caption, continued: "rium obſervata Romæ," *solar [?], observed at Rome*; "usti, ad 28 ejusdem." *August [?], to the 28th of the same [month]*. Drawings: *23* (before the fold); *24*, *25*, *26*, *27*, *28*, each with *a*.
- Row VIII. Caption, continued: "larium obſervata Romæ," *solar [?], observed at Rome*; "Octob. ad 10 Novemb." *[?] October, to 10 November*. Drawings: *5*, *6*, *7*, *8*, *9*, *10*, each with *c*.
- Lower right, inside the plate mark: "Autor ſculpsit." *Engraved by the author.*

And these are the genuine, and indeed the most conspicuous, properties of the solar spots; and it is plainly in this way that they arise, subsist for some time in the aether, and set in their own time, with no spot at all contradicting it. But so that the matter may be made still clearer, and the most eager investigator of the secrets of nature may be satisfied all the more, and his thirst in some measure quenched — especially since it is also most expedient for our present purpose, where we are to treat of the genuine physical rising and setting of comets and of other matters bearing on this — we have decided to display, in certain figurations, various periods of the spots, acquired from the sky itself at different times with the utmost diligence and delineated, as much by Scheiner as by ourselves. By means of these spots, everything that has been asserted in the preceding aphorisms can be clearly demonstrated.

[Margin: Figurationibus, & exemplis quibusdam res elucidatur, ac asſertiones omnes ſuperiores ſtabiliuntur.] *The matter is elucidated by figurations and certain examples, and all the assertions above are established.*

Above all, however, in these delineations of the spots I shall work to this end: that I depict exactly such [spots] in which their first generation, accretion, augmentation, coalition, condensation, and the packing together of their nuclei appear exquisitely and clearly; likewise, by what way their dissolution, rarefaction, segregation and diminution come about in turn; and then by what means they are at last entirely extinguished and vanish — in accordance with our assertions 3, 5, 6, 7, 8, 9, 10, 11, 12, 13, 17 and 23. For to comprehend and elucidate each and every case in so few figures is a thing altogether impossible. Whatever is not contained in these diagrams, however, can be deduced with the greatest ease from the very sources of the observations. For nothing at all has been asserted by us that is not supported by sure experience of things and derived from the most approved observations.

[Margin: In delineationibus inprimis progreſſio generationis,& diſſolutionis attenditur.] *In the delineations attention is paid above all to the progression of generation and of dissolution.*

Next, so that we may sketch the progression of the generation and dissolution of the spots the more accurately, we have not wished always to keep exactly the same size for them as was depicted in the originals, but have taken it somewhat larger, while preserving, as far as we could, the due proportion. Nor have we resolved to observe so strictly and constantly their daily motion, or how much space they actually completed in the course of their journey; rather, we shall give the spots drawn as if they had travelled equal paths on each single day, that motion — unequal [and] optical [?] by reason of the rotation of the Sun — being entirely set aside. As for that other motion, however, the spots' own proper and natural anomalous one, care will be taken that it is duly expressed, as far as can be done. Moreover, I do not wish you to be unaware that we have also deliberately neglected the annual inclination of the trajectory, convex at certain times and concave at others with respect to us; and that in all the delineations we have represented the path of the spots by straight lines only. For on this occasion we are concerned not with the line of advance, nor with the motions of comets (which is reserved for elsewhere), but with how the varieties and vicissitudes of generation and corruption may be demonstrated correctly and clearly; and this will be accomplished best of all only by straight lines. If anyone, however, burns with the desire to understand that motion, let him consult the *Rosa Ursina*, the *Selenographia*, and above all Book IX of this our *Cometographia*; I do not doubt that he will be thoroughly instructed.

[Margin: Quid porrò in Iconiſmis notandum ſit.] *What is further to be noted in the figures.*

[Margin: De generatione & corruptione Macularum Solarium.] *On the generation and corruption of the solar spots.*

From these sixteen periods of the solar spots, therefore, drawn accurately for each single day of their appearance, partly by Scheiner and partly by ourselves, it is per- spicuous that all the spots are first coagulated from the most tenuous and rarest solar matter, and at last resolved into the same once again. This appears clearly above all from those that had their beginnings on the visible hemisphere of the Sun and ceased to exist there again: namely, from the appearance of the solar spots III, IV, V, VII, VIII, XIII, XIV and XVI. The matter, that is, more dilute at first, gradually coalesces; then it is brought into a denser [state]; afterwards very small nuclei are created, which at length grow successively into a great mass, and into very dense and very vast bodies. Now several are produced from a single one, now one very compact and more solid from several; and they vary from day to day, indeed not rarely from hour to hour, now joining together and growing, now separating and decreasing, and they undergo truly wonderful and astonishing alterations and changes — just as has been set out in the aphorisms above, and as the observations themselves also declare.

[Margin: Breviſſimo temporis ſpatio, circa maculas admirandæ exoriuntur mutationes, & alterationes.] *In a very short space of time wonderful changes and alterations arise in the spots.*

But what form each spot continuously put on day by day, whether in growing or in decreasing, there is no need to recount here at greater length, since any period of the spots whatever shows it plainly enough, provided it is looked at not with a fleeting eye but with a fixed one. You will no doubt be amazed that within so short a time — the space of a few days, indeed of hours — they are subjected to such wonderful and dreadful changes and vicissitudes. How, moreover, can it ever happen that from such extremely dilute exhalations and effluvia spots and nuclei can be generated as various and dense as they are of wonderful size, as the delineations of the spots II, III, V, VI, IX, XII and XV especially show? But whatever the case may be, all the observations demonstrate that it truly is so. Therefore, if anyone does not yet grasp the individual points, nor believes them, he will be able, if he pleases, to test the same things himself, and so every doubt will be removed.

In an entirely similar way, as you have perceived and see clearly from the very figures of the spots, it is also with comets and with their generation and corruption. For they likewise have a slender beginning from the most subtle matter of the planets, which is expired and ejected from those same bodies, first into the surrounding atmosphere; and then also, according to the suitability of the matter, it is thrust out by that route (by what route, you will learn in Book Nine) into that great sea of the aether. There, in time, it is gradually coagulated [?], grows, is condensed, is joined with other vapours of other planets arriving and meeting it from here and there, and is packed together by them; at length that cometic body is reduced into a very dense mass, and at times into very opaque nuclei. Finally, according to the constitution and abundance of the effluvia, they are preserved in vigour for some time. At last, however, the

comet begins to be dissolved and its matter to be attenuated — not so uniformly, nor in the same way at every time, but now in this way, now in another: now they are reduced into several larger nuclei, now into many smaller ones; and so at last they pass away once more into the most tenuous matter, by no means perceptible to us.

[Margin: QuomodoCometæ naſcantur, & creſcãt; decreſcant, ac intereant.] *How comets are born and grow, decrease and perish.*

Here, however, it must be noted that comets, as happens with the spots, do not always display the same figure or appearance while they grow and decrease, but frequently degenerate, now from a round figure into an elliptical one, now into some other angular and irregular one, according to the proportion of the matter that from time to time increases or decreases. And hence it happens that some co-

[Margin: Cometæ, ut Maculæ figuram ſæpiùs mutant.] *Comets, like the spots, rather often change their figure.*

Diagram. Engraved folding plate, "Fig. E", of which this page shows the left part; the rest of the same plate is the next page. Eight bands of drawings of spots run across the plate, each headed at the right by a two-line caption that begins with its Roman number, IX to XVI: "Facies Macularum …" *Appearance of the spots …*, then "Anno …" *in the year …* with a starting date. Beside each caption the drawings stand in a line, each with an engraved number above it and one or more small letters beside it. The spots are drawn as hatched dark cores, several inside dotted or lightly hatched outlines (bands IX to XI and XIII), some as scattered clusters of small dots, and in band XVI as round cores inside stippled rings. Near the right edge of this part a vertical fold crosses the whole plate; beyond it only a narrow strip of the next panel shows. Every caption runs into the fold, so the end of each caption is not read here. "Fig. E" stands at lower left. All labels on this part of the plate are listed below; none is supplied from the text.

- Band IX. Caption: "IX Facies Macularu" *IX. Appearance of the spots* [?]; "Anno 1625, à 1" *in the year 1625, from 1* [?]. Drawings: *19*, *21*, *22*, *23*, *24*, each with *a*; *5* (beyond the fold).
- Band X. Caption: "X Facies Macularu" *X. Appearance of the spots* [?]; "Anno 1625, à 27" *in the year 1625, from the 27th* [?]. Drawings: *27*, *28*, *29*, *30*, *31*, each with *a*; *1* (beyond the fold).
- Band XI. Caption: "XI Facies Macularum" *XI. Appearance of the spots* [?]; "Anno 1626, à 15" *in the year 1626, from the 15th* [?]. Drawings: *15*, *16*, *17*, *18*, *19*, each with *c*.
- Band XII. Caption: "XII Facies Macularum" *XII. Appearance of the spots* [?]; "Anno 1626, à" *in the year 1626, from* [?]. Drawings: *21*, *22*, *23*, each with *a*, *c* and *b*; *24*, with *a*, *c* and *b*, and then *a* and *c* beside a large spot that follows; *25*, with *b*; beyond the fold, a number beginning with 2 [?], then *a* and *c*.

- Band XIII. Caption: "XIII Facies Macularu" *XIII. Appearance of the spots* [?]; "Anno 1643, à Di" *in the year 1643, from the d[ay]* [?]. Drawings: *14*, *15*, *16*, *17*, each with *e*; a further *e*; *18*, with *e*; beyond the fold, a letter cut by the edge [?].
- Band XIV. Caption: "XIV Facies Macularu" *XIV. Appearance of the spots* [?]; "Anno 1644, à 11" *in the year 1644, from the 11th* [?]. Drawings: *10*, *11*, *12*, *13*, *14*, each with *g*; *15* (beyond the fold).
- Band XV. Caption: "XV Facies Macularum" *XV. Appearance of the spots* [?]; "Anno 1644, à 4" *in the year 1644, from the 4th* [?]. Drawings: *4*, *6*, *7*, *8*, each with *d* and *e*; a mark in the fold [?].
- Band XVI. Caption: "XVI Facies Macularum" *XVI. Appearance of the spots* [?]; "Anno 1644, à Die" *in the year 1644, from the day* [?]. Drawings: *16*, *22*, *23*, *24*, each with *a* and *b*.
- Lower left: "Fig. E"

Fig. E, right part. This page shows the right part of the same folding plate Fig. E described on the previous page: a narrow strip of the left part, the fold, and then the rest of the eight bands, each caption running on from the left part. All labels on this part of the plate are listed below; none is supplied from the text.

- Band IX. Caption, continued: "olarium obſervata Romæ," *solar [?], observed at Rome*; "rilis, ad 30 ejusdem." *19 April [?], to the 30th of the same [month]*. Drawings: *5* (at the fold); *26*, *27*, *28*, *29*, *30*, each with *a*.
- Band X. Caption, continued: "Solarium obſervata Romæ," *solar, observed at Rome*; "sti, ad 6 Septembris." *August [?], to 6 September*. Drawings: *1* (at the fold), *2*, *3*, *4*, *5*, *6*, each with *a*.
- Band XI. Caption, continued: "Solarium obſervata Romæ," *solar, observed at Rome*; "br. ad 25 ejusdem." *[?], to the 25th of the same [month]*. Drawings: *20*, *21*, *22*, *23*, *24*, *25*, each with *c*.
- Band XII. Caption, continued: "larium obſervata Romæ," *solar [?], observed at Rome*; "21 Maji, ad 30 ejusdem." *the d[ay]* [?] *21 May, to the 30th of the same [month]*. Labels, left to right: a letter cut by the edge of the image [?]; *2*; *c*; *26*; *b*; then *a*, *c*, *27*, *b*; *a*, *c*, *28*, *b*; *a*, *c*, *29*, *b*; *a*, *c*, *30*, *b*.
- Band XIII. Caption, continued: "Solarium observata Gedani," *solar, observed at Danzig*; "Augusti, ad 24 ejusdem." *the day 1…* [?] *August, to the 24th of the same [month]*. Drawings: two marks in the fold [?]; *19*, *20*, *21*, *22*, *23*, *24*, each with *e*.
- Band XIV. Caption, continued: "Solarium obſervata Gedani," *solar, observed at Danzig*; "lis, ad 19 ejusdem." *April [?], to the 19th of the same [month]*. Drawings: *15* (at the fold), *17*, *18*, *19*, each with *g*.
- Band XV. Caption, continued: "larium obſervata Gedani," *solar [?], observed at Danzig*; "i, ad 15 ejusdem." *May [?], to the 15th of the same [month]*. Drawings: *10* (before the fold), *11*, *12*, *13*, *14*, *15*, each with *d* and *e*.

- Band XVI. Caption, continued: "rium obſervata Gedani," *solar [?], observed at Danzig*; "Maji, ad 28 ejusdem." *the day 1… [?] May, to the 28th of the same [month].* Labels, left to right: a mark in the fold [?]; *a*, *25*, *b*; *a*, *26*, *b*; *a*, *27*, *b*; *a*, *28*, *b*; *29*, *b*; *30*, *b*.
- Lower right, inside the plate mark: "Autor ſculpsit." *Engraved by the author.*

met, in the course of time abandons its first appearance and form and assumes an entirely different one. Such was the comet that shone forth in the year 348 before the birth of Christ, as Pliny the Elder attests, book II, chapter 25. For he says: *Only once so far has the likeness of a trumpet been changed into a spear, in the hundred and eighth Olympiad, in the three hundred and ninety-eighth year of the City.* So from an equine [comet] the comet became spear-shaped. Without doubt many others of this kind have existed, had they only been carefully recorded by the ancient authors. It is therefore not unreasonable that comets can at times change their appearance and tail, according as matter and nuclei grow onto the head from this side or that, or depart more or less from one side or the other, or are dissolved more quickly or more slowly; but more on these matters elsewhere.

[Margin: Exemplis comprobatur.] *It is confirmed by examples.*

Now, my astrosopher, we shall take pains to set before everyone's eyes, after the likeness of the solar spots, the physical rising and setting of comets likewise, clearly and indeed graphically: namely, how their generation and corruption really takes place, or can take place. To carry out this task the more accurately, the comets of the years 1618 and 1652 will light the way for us, as will a third, which shone recently, in the year 1661, in the month of February; for all the others were not properly observed, nor could they be observed, since at that time the use of telescopes was not yet available. Meanwhile, however, whatever will be asserted about those three, that, I say, we wish to be said of all in general. Let us, then, consider them and sketch them just as they were observed with the help of the optical tube on various successive days, and indeed after the example of the solar spots, which cast towards us not at all the borrowed light of the Sun, but only the shadow of their own body. For since they are entirely opaque bodies, the Sun cannot pierce them through with its rays; rather, they are illuminated only on the side turned towards the Sun and away from us. Comets, on the contrary, almost always show us an illuminated face, the other always remaining invisible, since at the time of conjunction they never come into our view, unless this should happen during some total eclipse of the Sun.

[Margin: Tribus cumprimis exemplis ortus & occaſus phyſicus Cometarum perquàm dilucidè demonſtratur.] *The physical rising and setting of comets is demonstrated very clearly by three examples above all.*

[Margin: Quâ ratione Cometæ iſti delineati fuerunt.] *In what way these comets were delineated.*

And so let us display the comets as if they were seen from the dark side, turned away from the Sun and from us, which can in no way be lit by the Sun;

or, what comes to the same thing, as if the comets were not imbued with the light of the Sun. Then, I say, the whole matter of the comets would appear very dark, like the solar spots; and so all the more solid and more compact parts would be seen as much darker than the more tenuous and more dilute ones. For in this way we shall see clearly that very close affinity which exists between comets and the spots with respect to generation and corruption, and also that nothing more similar can either be given or be imagined. Moreover, [we shall see] that comets as well as spots have an entirely similar character as regards their first origin and their last appearance or dissolution; and also that with those very minute things which cannot yet be noted so accurately in the generation and corruption of comets, it truly stands in the same way as with their more notable increase and decrease.

[Margin: In quibusdam, Cometæ ſimiles ſunt Maculis Solaribus.] *In certain respects comets are similar to the solar spots.*

But to come to the comet of the year 1618 itself, I would have you know that it was observed by Cysat with the help of the telescope not on every single day, but only on some days: namely on 1 December, when, entirely fiery and very bri- ght, it stood out; on the 8th, when it was already decreasing; and on the 17th, 18th, 20th and 24th, when it was already found to be very dark. For these days we have given this comet, correctly drawn, in the attached diagram under the letters E F G H, just as Cysat delineated it in his booklet and carefully described it, but in our own manner: namely, the parts that seemed to him brightest, like little stars, are for us opaque corpuscles and denser nuclei. From the first observation it is clear that the cometic head consisted of a single very dense nucleus, or, if of several, of ones nevertheless closely adhering to one another. This nucleus, however, on 8 December passed into three equally solid ones, and also, without doubt, into other more tenuous ones, as is sketched in figure F; on the 17th and 18th, again, they were reduced into more [nuclei] and into rarer matter; then, on the 20th and 24th, they were successively cut up into far more corpuscles, very minute ones, and dissolved into very dilute evaporations, with a very thin shadow sprinkled here and there, as the delineations clearly show. Hence we rightly conclude that this progress of the nuclei and of the matter, in respect of dissolution and attenuation, detected from 1 December up to the 24th, was continued steadily more and more on the following days and went on unremittingly in that decrease, as is established from Cysat's own observations: namely, that the comet was noticed to be paler day by day and larger as to its diameter. It could not, therefore, have happened otherwise than that the corpuscles and nuclei were gradually separated, and that the matter lying between them also became little by little rarer and more dilute by moving apart and spreading itself out, until the whole mass and heap was entirely dissolved into mere shadows and very subtle evaporations, or a very tenuous aethereal air, like the solar spots.

[Margin: Quâ ratione caput Cometæ 1618 indies creverit,ac immutatum fuerit.] *In what way the head of the comet of 1618 grew day by day and was changed.*

Since, therefore, this comet strictly kept to such a process in decreasing, around its physical setting, we certainly argue rightly (bearing in mind above all that a generation and corruption entirely similar to that of the solar spots, and perpetual, takes place) that the phenomenon also held to exactly the same progress in growing, around its first physical rising: namely, that the cometic body took its origin from the most subtle matter of the planets, which, gradually condensed, was gathered into various growing nuclei, so that at last it turned into a great mass and a remarkable nucleus, according to our fifth assertion: that is, by the concourse of like matter to like, by condensation, by adgeneration, by substantial generation, and by the aggregation of very many most minute corpuscles. This variation of the matter, and the manifold alteration of the corpuscles, we have expressed in certain diagrams [Schematiſmis] B C D, as we judge all those things to have happened.

[Margin: Cometæ ferè eâdem ratione ut creſcunt,ſic & decreſcunt.] *Comets decrease in almost the same way as they grow.*

Now, then, judge for yourself, I beg you: has everything been presented properly, according to the mind of the observer and the tenor of the observations themselves? And are comets also exceedingly similar to the solar spots? Indeed, comets agree with the spots of the Sun not only to the greatest possible degree in generation, increase, diminution and corruption, but also in almost all their remaining properties, as we shall demonstrate more fully below.

[Margin: Summam convenientiam intercedere inter Cometas, & Maculas ultrò agnoſcent omnes.] *All will readily acknowledge that the greatest agreement exists between comets and the spots.*

Now let us approach the comet of the year 1652 and its physical rising and death; but it would be desirable that observing it more often with the telescope had be-

Diagram. Engraved folding plate, "Fig. F.", of which this page shows the left part; the rest of the same plate is the next page. Six bands of round drawings of comet heads run across the plate. Each band is headed by a caption line set towards the right, beginning "Cometa Anno" *Comet in the year*, and a line of dates, one date over each drawing; in the first two bands capital letters also stand over some drawings. The heads are drawn as discs of horizontal hatching: some carry a single dark, cross-hatched nucleus inside a pale ring, others several dark clusters, others only faint streaks and specks. Near the right edge of this part a vertical fold crosses the whole plate; beyond it only a narrow strip of the next panel shows, and every caption runs into the fold, so the end of each caption is not read here. "Fig. F." stands at lower left. All labels on this part of the plate are listed below; none is supplied from the text.

- Band 1. Caption: "Cometa Anno 1618 à" *Comet in the year 1618, à*, followed by letters broken by the fold [?]. Over the drawings, left to right: *B*; *C*; *D*; "1 Decemb." *1 December*, with *E*; *8 December* [?], with *F*; *17 D…b.*, the middle of the word lost in the fold [?]; over the sixth drawing, beyond the fold, a short mark that is not read [?].

- Band 2. Caption: "Cometa Anno 1652" *Comet in the year 1652*, followed by a, a letter broken by the fold, and a word beginning "Au" beyond it [?]. Dates: "15 Decemb." *15 December*; "18 Decemb." *18 December*; "20 Decemb." *20 December*, with *D*; *27*, then letters broken by the fold, *…ece…* [?], with *E* beyond the fold.
- Band 3. Caption: "Cometa Anno 1661" *Comet in the year 1661*, followed by a, a letter broken by the fold, and a word beginning "Au" beyond it [?]. Dates: "3 Februar." *3 February*; "5 Februar." *5 February*; "6 Februar." *6 February*; "7 Februar." *7 February*; "10 Februar." *10 February*; at the fold a figure ending in 3 and the capital F of a month [?].
- Band 4. Caption: "Cometa Anno 1664 et" *Comet in the year 1664 and* [?] *665*, the first figure of the second year lost in the fold. Dates: "14 Decembr." *14 December*; "18 Decemb." *18 December*; "21 Decemb." *21 December*; "28 Decemb." *28 December*; "29 Decemb." *29 December*; *30 Dece…*, cut by the fold [?]; beyond the fold, a date beginning with 3 [?].
- Band 5. Caption: *Comet in the year[s]* [?] *1664 and* [?] *65*, the first figures of the second year lost in the fold. Dates: "9 Januarii." *9 January*; "10 Januar." *10 January*; "17 Januar." *17 January*; "19 Januar." *19 January*; *20 Jan…*, cut by the fold [?].
- Band 6. Caption: "Cometa Anno 1665" *Comet in the year 1665*, followed by a, strokes in the fold, and the letters ctor beyond it [?]. Dates: "6 Aprilis." *6 April*; "7 Aprilis." *7 April*; "8 Aprilis." *8 April*; "10 Aprilis." *10 April*; "11 Aprilis." *11 April*; *13 Ap…*, cut by the fold [?]; beyond the fold, *14* and a stroke not read [?].
- Lower left: "Fig. F."

Fig. F, right part. This page shows the right part of the same folding plate Fig. F described on the previous page: a narrow strip of the left part, the fold, and then the rest of the six bands, each caption running on from the left part. All labels on this part of the plate are listed below; none is supplied from the text.

- Band 1. Caption, continued: letters at the fold [?], then "ato obſervatus." *…ato* [?], *observed*. Labels: *D…*, cut at the fold [?]; a mark in the fold over the cut drawing, not read [?]; "24 Decemb." *24 December*, with *H*; two further drawings with no date or letter.
- Band 2. Caption, continued: "ctore observatus." *observed by the Author* [?], the first letters of the noun at the fold. Labels: *D…b.*, cut at the fold [?], with *E*; "30 Decemb." *30 December*, with *F*; *3 January* or *8 January*, the figure not settled [?], with *G*; "6 Januar." *6 January*, with *H*; *I* standing above "10 Januar." *10 January*.
- Band 3. Caption, continued: "ctore obſervatus." *observed by the Author* [?], the first letters of the noun at the fold. Dates: a figure ending in 3 and the month's capital lost at the fold, then "ebruar." *February* [?]; "17 Februar." *17 February*; "20 Februar." *20 February*; "2 Martii." *2 March*, set higher than the band's other dates.

- Band 4. Caption, continued: a figure ending in 5 and letters at the fold [?], then "ab Auctore obſervatus." *observed by the Author*. Dates: faint letters in the strip before the fold, not read [?]; *December*, its figure lost at the fold [?]; "1 Januar." *1 January*; "3 Januar." *3 January*; "5 Januar." *5 January*; "7 Januarii." *7 January*.
- Band 5. Caption, continued: figures at the fold, of which a 6 is read [?], then "ab Auctore obſervatus." *observed by the Author*. Dates: faint letters in the strip before the fold, not read [?]; "21 Januar." *21 January*; "23 Januar." *23 January*; *30 January* or *80 January*, the first figure not settled [?]; "3 Februarii." *3 February*.
- Band 6. Caption, continued: a, then strokes at the fold [?], then "tore obſervatus." *observed by the Author* [?]. Dates: *Ap…*, cut at the fold [?]; "14 Aprilis." *14 April*; "15 Aprilis." *15 April*; "16 Aprilis." *16 April*; "18 Aprilis." *18 April*; "20 Aprilis." *20 April*.
- Lower right, inside the plate mark: "Autor ſculpsit." *Engraved by the author.*

fallen [us]; as to that, since it in fact happened only once, let us call to our aid the [observations] of others, namely those of Wendelen and also of the Jesuit Fathers, made in Italy and presented in Book IV, p. 328. First, under the letters E and D you have the comet's true face, which it presented to me on 27 December and to Wendelen on the 20th of the same month. Next, under the letters H and I, [you have] the form the comet had on 6 and 10 January, when, like a shadow, a cloud, and very fine corpuscles and dispersed rarer matter, it appeared stripped and bare of all its nuclei entirely, according to the observations we presented in Book VI, p. 327.

[Margin: Quâ rationeCometa an. 1652 incrementa, & decrementa ſua ceperit[?]] *How the comet of the year 1652 took its increases and decreases.*

Since, therefore, from 27 December to 10 January the comet's nuclei, or more solid corpuscles, decreased greatly, and its matter became far rarer and more extended, so that in the end nothing but shadows and very dilute effluvia were observed, it necessarily follows that on the intervening days too the comet decreased, and that the matter of which it was composed was gradually thinned. Moreover, since every decrease, not only in the solar spots but in any natural things whatever, takes place continuously, gradually and successively, it is not wrongly judged that it happened entirely so in this comet too. Its decrease, and the alternation and change of its corpuscles and matters from 20 December up to its death, we have carefully depicted according to our own view in the preceding figure under the letters F and G: namely, how the comet became from day to day truly more dilute and yet larger as to its head, and was at last resolved into the finest matter.

[Margin: Nuclei hujus Cometæ paucis diebus valdè decreverunt.] *The nuclei of this comet decreased greatly within a few days.*

[Margin: Conſequentia infallibilis.] *An infallible consequence.*

I consider that things happened no differently at its first birth and growth: so that its matter, at first very dilute, successively became denser, and was at last also transformed into more solid nuclei, with rarer matter adhering here and there, as is clear from the figure. Yet this difference existed between the two comets: the earlier consisted of larger and more solid nuclei, the later of smaller and thinner ones, not even excepting the day of 20 December itself, when it seemed to have reached its very greatest maturity. Accordingly it also appeared far paler and darker than the earlier comet, exactly like the solar spots that arise from smaller nuclei and rarer matter, which at all times likewise show a leaden hue and a paleness on the Sun's disc.

[Margin: Quid differentiæ intercedat inter Cometam 1618 & 1652.] *What difference exists between the comet of 1618 and [that of] 1652.*

[Margin: Vnde Cometa 1652 pallidior extiterit Cometâ 1618.] *Why the comet of 1652 was paler than the comet of 1618.*

That the comet of the year 1652 did not possess equally dense and large nuclei came about, as far as can be gathered, from no other cause than that suitable matter of that kind was lacking; or that those vapours were at that time subtler and paler than others; or rather that the expirations of Saturn, Jupiter, Venus and the Moon, if I am not mistaken, prevailed in this comet, and these perhaps do not seek condensation as much as those of the Sun, Mars and Mercury do. For the Sun's matter above all, as is evident from the spots, is very prone to coagulate and condense, and, as it seems to us, is like a glue that binds together and unites the vapours of all the other planets. To the extent, therefore, that more or less of this solar matter flies together to the comet and adheres to it, to that extent the comet is made denser and more compact. But these things are gathered only by conjecture;

[Margin: Quantò plùs exhalationis Solaris Cometæ ineſt, tantò denſius compactiusq́; ejus corpus eſſe conjicitur.] *The more solar exhalation there is in a comet, the denser and more compact its body is conjectured to be.*

since they cannot be deduced. Just as it cannot be grasped with certainty why this or that spot of the Sun is larger and more solid than the rest, and why our clouds are not always equally dense and dark, it is no wonder, then, if those matters are likewise placed among the number of things that cannot yet be adequately perceived.

But the progression of the coagulation, augmentation, accretion, dissolution and decrease of comets will become much clearer still to everyone from the comet of the year 1661, famous for its varied and rare phenomena, which shone in the month of February; we have resolved, with God's help, to set out its observations and its whole history toward the end of this work. For I observed it twelve times, on different days, with an excellent and very long telescope, and each time I also sketched its face at once, properly and with the greatest attention. My purpose was to learn accurately the shape of the head, the arrangement of the nuclei, and also each change from day to day, and to show them to others devoted to celestial matters, as we have set out at greater

length in the general description of the same comet. From that description I shall now add here, only briefly, in what appearance it showed itself with respect to its matter, nuclei, light and colour, so that it may be understood the more readily how its head varied, and that I drew the likenesses of it placed in the preceding Figure not at my pleasure, out of my own head, but from the very sources of the observations.

[Margin: Ex Cometâ an. 1661 ortus & occaſusCrinitarum Stellarum adhuc clariùs cognoſcitur.] *From the comet of the year 1661 the rising and setting of the hairy stars is known still more clearly.*

Observations of the Comet of the Year 1661 [Obſervationes Cometæ anni 1 6 6 1.]

1. In the year 1661, on 3 February. The head was of a yellowish colour, bright and conspicuous, yet it had no twinkling light. In its middle it showed one dense and reddish nucleus, almost equal to Jupiter itself; this, however, was surrounded by far more dilute and thinner matter.

[Margin: Obſervation[[e/è]]s Cometæ anni 1661.] *Observations of the comet of the year 1661.*

2. On 5 February. The head [was] somewhat larger and brighter, of the colour of gold; its light, however, appeared gloomier than that of the other stars. But that single nucleus had already been cut into several parts, as the drawing of this day under the letter F shows.
3. On 6 February. The comet still showed almost the same colour, not unlike, though somewhat duller than, the colour that the star in the shoulder of Aquila displays at other times. The disc had partly decreased, and most of the nuclei were also smaller; one of them, in the lower part of the disc toward the left, was much denser and brighter than all the rest, with a round body, like some very bright little star. Other matter, as always, entirely surrounded these nuclei.
